In comparing biofeedback to PME, the approaches have been found to have comparable results. In a randomized controlled study, Burns et al. (1993) studied 135 women (age range 55–75 years) with primary stress incontinence. One treatment group received PME, and another group received single-measurement biofeedback for 20 minutes per week. The two treatment groups demonstrated a 54–61% reduction in incontinent episodes, compared with a 6% reduction of UI in a control group. No significant difference between the two treatment groups was found. This study demonstrated that both PME and biofeedback have the potential to reduce UI, and provided evidence that symptom severity has a role in response.

(ii) Pelvic muscle rehabilitation: weight training

Specially designed vaginal weights to strengthen the pelvic muscles have also been used to supplement PME. In this therapy, the patient receives a set of vaginal weights of identical shape and volume but of increasing mass. As part of a progressive resistance program, women insert a weight intravaginally and are instructed to attempt to retain it by contracting the pelvic muscle for up to 15 minutes at least twice daily. It is to be worn while the patient is ambulatory. The mechanism of action that the sustained contraction requires to retain the weight increases the strength of the pelvic muscles in a way that provides heightened feedback as to the desired pelvic muscle contraction. Available literature on this technique includes observations made in women with stress incontinence, but no controlled trials have been conducted. Initial observation from four anecdotal studies indicate a subjective cure rate or improved status in 68–80% of women after 4–6 weeks of treatment (Bridges, Denning, Olah, & Aorrar, 1988). The preliminary data from vaginal weight training, as well as the simplicity of the procedure, make it an attractive treatment option. However, the procedure is not yet well evaluated and further research is needed.

7.19.5.3.3 Toileting assistance protocols

Toileting assistance interventions are necessary for many physically impaired people who cannot independently toilet and for cognitively impaired people who cannot remember the behaviors necessary to maintaining continence (e.g., finding the bathroom). Most of the estimated one million nursing home residents who suffer from UI have both physical and cognitive problems that prevent independent toileting. Therefore, it is necessary that their caregivers provide some level of assistance to compensate for the resident's deficits. Unfortunately, many of these cognitive and physical problems are not reversible in the nursing home population, and it is necessary that caregivers continue to provide toileting assistance indefinitely. Thus, the goal for most cognitively impaired patients is to increase dryness under conditions where staff or other caregivers implement a routine protocol. This is in contrast to less impaired populations, in which the goal is to rehabilitate patients to the point where they are capable of maintaining dryness independently. Several toileting assistance protocols have been described for application in nursing homes.

(i) Routine or scheduled toileting

Routine or scheduled toileting is conceptually the most simple toileting assistance procedure, and involves the caregiver placing the patient on the toilet every 2–4 hours. No systematic effort is made to have the patient delay voiding or to have him or her initiate or ask for toileting assistance, and there are relatively few mobility requirements. There are no controlled trials of scheduled toileting procedures, even though there have been some reports that it has positive effects (Burgio et al., 1989).

(ii) Habit training

Habit training is a modification of the scheduled toileting protocol in which caregivers first attempt to identify a resident's voiding pattern. A toileting schedule is then set based on this voiding pattern. Presuming predictable voiding habits can be identified, placing a patient on a toilet at the point that they are most likely to void should prevent UI episodes. One study has reported positive results with this procedure (Colling, Ouslander, Hadley, Eisch, & Campbell, 1992).

(iii) Prompted voiding

The toileting assistance protocol that has been most thoroughly evaluated is prompted voiding. The major objective for prompted voiding is to establish an awareness on the part of the patients as to their continence status (wet or dry) and to increase the probability that they will ask for toileting assistance. Residents are not placed on the toilet unless they respond to a prompt for assistance or self-initiate a request for toileting assistance. The major steps in prompted voiding are listed in Table 3. It should be noted that these steps are deceptively simple. Many nursing home residents show severe communication and attention problems, and therefore a high level of clinical skill is required to induce them to respond to prompts. A behavioral training program in which caregivers are taught to orient residents to questions with a series of verbal and manual prompts greatly increases the ability of caregivers to teach cognitively impaired residents to respond affirmatively to prompts.

Prompted voiding has been documented to be highly effective in nursing home residents when skilled staff implement the protocol, even with residents who have different types of urinary tract dysfunction (Schnelle, Newman, Abbey, et al., 1990). Data collected during three major clinical trials indicate that 25–45% of incontinent residents will respond to prompted voiding, with a reduction in their UI frequency from three to four episodes per day to one per day (Schnelle, 1991; Schnelle & Ouslander, 1996). Approximately 34–40% of these residents do not respond, either because of their refusal to respond to prompts, or their inability to initiate voiding once they are assisted to the toilet. Severe depression and cognitive impairment often characterize those residents who refuse to respond to prompts. Problems in the lower urinary tract characterize residents who cannot initiate toileting once on the toilet. Procedures to identify residents who are capable of responding to prompts, initiating bladder emptying when on the toilet, and maintaining dryness have been described, and responsive residents can be identified in a three-day run-in trial (Ouslander et al., 1995b). This run-in assessment procedure is described in more detail in Section 7.19.6.1.

Unfortunately, there is strong evidence that prompted voiding procedures are not consistently implemented by indigenous nursing home staff, even with residents who are highly responsive (Schnelle, Newman, & Fogarty, 1990a). The inconsistent application of the prompted voiding procedure invariably results, even with the most responsive residents, in an increase in UI frequency, since few nursing home residents are capable of independent toileting. The primary dynamic that causes staff to gradually withdraw toileting assistance and decrease implementation of prompted voiding relates to time

Table 3 Prompted voiding protocol.

1. Contact the residents every two hours from 7 a.m. to 7 p.m.
2. Focus residents' attention on voiding by asking them whether they are wet or dry
3. Check resident for wetness, record on bladder record, and give feedback on whether the resident's self-report was correct or incorrect
4. Whether wet or dry, ask the residents if they would like to use the toilet (or urinal).
   (a) If they say yes:
      (i) Assist them
      (ii) Record the results on the bladder record
      (iii) Give them positive reinforcement by spending an extra minute or two talking with them
   (b) If they say no:
      (i) In the event they have not attempted to void in the last four hours, repeat the request to use the toilet once or twice before leaving, and follow step 4(a) if an affirmative response is received
      (ii) Inform them that you will be back in two hours and request they try to delay voiding until then

efficiency (Schnelle, 1991; Schnelle, Sowell, Hu, & Traughber, 1988a). It has been documented many times that changing residents when they are wet is less time consuming for staff than is prompting them with sufficient frequency to maintain dryness (Schnelle, Sowell, Hu, & Traughber, 1988b). Furthermore, a resident is typically changed one to two times per eight-hour shift, despite best practice guidelines, and a successful prompted voiding program would require that a resident be prompted four times and provided toileting assistance approximately three of those times. It has been calculated that the time staff spend in managing incontinent patients is approximately seven minutes per eight-hour shift, whereas to implement the prompted voiding program so as to maintain dryness would take approximately 26 minutes per eight-hour shift (Schnelle et al., 1995).

Due to the time dynamic and other factors, behavioral management systems that reinforce nursing home staff to maintain prompted voiding protocols have proven necessary if the protocols are to be maintained. The most successful of these management systems is based on applied behavioral analysis strategies and work sampling systems that are used in the area of total quality management. This management system and issues relevant to implementing the system will be described later in this chapter (Schnelle, Newman, et al., 1993).

The successful implementation of the prompted voiding protocol in nursing homes within the framework of the best-practice guidelines, describing how UI should be assessed, generates major opportunities for the involvement of a behaviorally trained professional. An algorithm that describes how UI can be successfully assessed and treated within the nursing home setting is provided in Figure 1. This algorithm is described below, with particular emphasis on those points in the algorithm that require the expertise of behaviorally trained professionals.

The first section of the algorithm covers the basic UI evaluation that is recommended by best-practice guidelines for all patients. This basic assessment was summarized earlier in this chapter, and it is fully described in the USAHCPR incontinence guidelines. A trained nurse can complete this part of the algorithm, and we will not discuss these basic assessment procedures again at this point.

However, we should note that experience indicates that many nursing home residents will show transient causes for their incontinence at this stage, but also that the management of these conditions will not result in the elimination of incontinence. Immobility and dementia are such powerful causative factors for UI in the nursing home population that a program to compensate for these problems is almost always necessary if UI is to be improved. The term "compensate" is used in the above sentence as opposed to "rehabilitate" or "reverse" since there is strong evidence that the cognitive and physical impairments that exacerbate UI are not reversible in most cases, given the current treatment technologies and resource availability.

The most important section of the algorithm for the treatment and management of UI is the quality assurance monitoring system. This system requires that nursing supervisors and staff be trained in basic principles of behavior management and quality control, and is

described later in the present chapter. First, we discuss the critical assessment stage associated with prompted voiding.

7.19.6 IMPLEMENTATION OF AN INCONTINENCE MANAGEMENT PROGRAM IN NURSING HOMES

7.19.6.1 Prompted Voiding Assessment

The most important section of the algorithm for the assessment of UI in nursing home patients is a three-day voiding, mobility, and behavioral evaluation. This three-day evaluation can best be done by nurses in combination with the behavioral health professional who is expert in the assessment of behavioral competencies and motivation.

Critical information is collected during this stage regarding the following issues.

(i) Will a resident be responsive to a prompted voiding program?

(ii) Is the resident motivated to be continent, but not responsive to the prompted voiding protocol because of problems with the lower urinary tract?

(iii) Can the UI symptoms and problems with the lower urinary tract be identified and treated in the resident who is motivated to be continent, but who cannot maintain dryness?

(iv) Does a resident have mobility or cognitive problems which preclude safe independent toileting and can these problems be treated?

(v) What form of UI measurement is best for the resident who does not appear to be either a candidate for further treatment or who appears to not want further treatment?

The major activity during this three-day trial stage involves exposing the residents to a prompted voiding protocol every two hours between 8 a.m. and 4 p.m. (four times per day for three days = 12 prompts). Data are recorded at each prompt relevant to a resident's incontinent status (wet or dry); the resident's response to prompt (attempted to toilet successfully, attempted to toilet unsuccessfully, did not attempt to toilet), and the resident's behavioral response to prompt (shows resistance, agitation, or cooperation).

Prior to this three-day trial, the resident should be asked the following questions.

(i) Does it bother you to wet in your diaper?

(ii) Do staff help you to the toilet as much as you would like?

(iii) Do you want to be helped to the bathroom more often?

If the resident answers no to question (iii):

(iv) Do you want to be helped to the toilet less often?

(v) Do you want to be changed more often? If the answer is no, ask question (vi);

(vi) Do you want to be changed less often? Immediately after the three-day trial, the resident should be asked the same questions plus the question:

(vii) Do you like the amount of changing and toileting assistance you have received in the last three-days?

The most critical statistic calculated during this trial is the resident's appropriate toileting percentage. Appropriate toileting is calculated by dividing the total number of successful toilets by the total number of toilets plus the number of incontinence voids. Thus, a 50% appropriate toileting statistic will be derived if a resident appropriately toileted during six of the prompts on the three days and was wet on six of the prompts. Two separate major trials have determined that residents who have appropriate toileting percentages above 66% will very likely continue to be continent if exposed to prompted voiding over longer intervals (Schnelle, 1990; Schnelle, Ouslander, & Simmons, 1993); thus, it is recommended that all residents who show an appropriate toileting percentage of 65% or above be placed on a prompted voiding program. Residents who have appropriate toileting percentages of less than 65% seldom show responsiveness with longer term applications of prompted voiding. Based on previous studies in several major clinical trials, approximately 30–40% of residents will show a 66% appropriate toileting percentage or higher during this three-day trial.

The resident's response to the six questions asked prior to and after the three-day trial coupled with his or her behavioral responses to the prompts provided during the trial form the information base used to evaluate a resident's motivation to be continent. Approximately 80% of incontinent residents can provide answers to these questions. Surprisingly, however, approximately 10–20% of incontinent residents in nursing homes show no behavioral or verbal willingness to be either changed or toileted more frequently. Such residents respond to the questions with answers which indicate that they are not bothered by wetness and do not want to be changed or toileted more often. Moreover, when efforts are made to change or toilet such residents on a two-hour schedule during the three-day assessment period, there is often both behavioral and verbal evidence that this UI care is unwanted. For example, direct quotes taken during conduct of the protocol are as follows: "It hurts. I don't want to use the bedpan." "Leave me alone. I don't want changed." Similar comments are heard with noticeable frequency. Residents who express this type of resistance will typically not attempt to toilet even if consistently prompted by skilled and clinically sensitive staff. It is to be remembered that in prompted voiding, residents are not placed on the toilet unless they respond affirmatively to a prompt.

Even though a case can be made that the behavior of these resistive residents is not appropriate and may be caused by psychological conditions such as conditioned helplessness or depression, further treatment for these residents is not indicated at the present time due to three factors:

(i) there are no leads as to what types of behavioral, psychological, or medical interventions could be successful with these resistive patients;

(ii) there are so many incontinent nursing home residents that we currently strain resources to treat and manage UI with even those residents who are motivated to be continent; and

(iii) there is a distinct chance that some residents have such a high sickness burden that they do not care about staying dry and would prefer to not go through the activities involved with toileting, in which case prompted voiding would hinder rather than benefit quality of life.

Research investigating why some residents no longer care about their UI condition is highly appropriate, but treatment should not be considered until such research is completed.

Approximately 10–20% of residents will not attain a 66% appropriate toileting statistic but will show behavioral and verbal evidence that they are motivated to be continent and thatthey want further treatment. Further evaluation for these residents is indicated. The most important behavioral evidence to identify residents in potential need of further treatment is a statistic that reflects their positive response to prompts and their attempts to toilet during the three-day period. This statistic is different from the appropriate toileting statistic which requires not only an attempt to toilet, but also a successful void. If the resident attempts to toilet two times per day, even if they are not successful, it is an excellent sign that they are motivated to be continent. Many residents who attempt to toilet unsuccessfully cannot initiate the voiding process once they are placed on the toilet. Others will attempt to toilet frequently and void small amounts, but will continue to be wet between the checks and hence will not attain a 66% appropriate toilet ratio. These residents very often show stress incontinence, detrusor instability, or detrusor instability with impaired contractility, all of which were discussed in Section 7.19.3.1. Further information is collected during this three-day period which is highly relevant to determining which of these types of incontinence a resident may have. The purpose is to identify all problems appropriately treatable by other interventions. These procedures will be described next.

7.19.6.2 Postvoid Residual Determination and Urinalysis

During the three-day run-in evaluation for prompted voiding, an attempt is made to collect urine for analysis and also to measure a resident's postvoid residual, as is recommended for the basic assessment of people who suffer from incontinence. The basic prompted voiding protocol is temporarily modified in order to obtain this information efficiently. For further efficiency purposes, an attempt is made to collect these data the first time the resident successfully toilets during the three days of prompted voiding rounds. This toileting event offers the opportunity to collect urine for analysis with either a "clean catch" technology or by catheterization if the resident has to be catheterized to measure the amount of urine left in the bladder after urination (postvoid residual).

Clean urine may be difficult to obtain from incontinent, cognitively impaired, immobile nursing home residents. However, one can often noninvasively obtain a "clean catch" urine that accurately matches culture results from a catheterized specimen. For a woman, the technique involves careful cleaning of the perineum with a sterile preparation and then having her void into a disinfected collection device (Ouslander, Schapira, & Schnelle, 1995). For a man, after the penis has been cleaned with a sterile preparation such as betadine, a clean condom catheter can be applied (Ouslander, Schapira, Fingold, & Schnelle, 1995).

The primary purpose of the urinalysis is to exclude hematuria unless the purpose is to investigate symptoms other than UI which are suggestive of a urinary tract infection (e.g., dysuria, recent onset or worsening of UI, unexplained fever or functional decline). The urinalysis can also exclude sterile hematuria, which may be a sign of bladder or upper urinary tract pathology, and glucosuria resulting from poorly controlled diabetes. In nursing home residents it is important to note that bacteriuria should not be treated, because such treatment consistently has been found to have no effect on the severity of UI in this population (Ouslander, Schapira, Schnelle, Uman et al., 1995).

Although rapid urine screening methods are generally thought of as inaccurate for nursing home residents, they can be used to exclude bacteriuria with reasonable accuracy. The combination of negative dipstick tests for both nitrite and leukocyte esterase and a negative enzyme-based screen for bacteriuria (Uriscreen) has a negative predictive value of over 95% for significant bacteriuria among incontinent nursing home residents (Ouslander, Schapira, Fingold, & Schnelle, 1995).

Significant degrees of urinary retention can occur in the absence of symptoms or signs of obstruction or bladder contractility problems. In addition, physical examination (suprapubic palpation, bi-manual examination) is neither sensitive nor specific in detecting significant residual volumes.

Postvoid residual volume is usually determined by catheterization, but a portable ultrasound device is now available that can provide a noninvasive measurement with reasonable accuracy (Ouslander et al., 1994). It is important to note that postvoid residual volume demonstrates substantial intra-individual variability. The timing of the determination in relation to a void, the degree to which the void was natural, the nature of instructions provided to the patient, the amount of straining, and body position can all influence this measurement. Thus, when moderately elevated volumes are detected (e.g., 150–300 ml), repeated determinations may be appropriate. In these situations in particular, the use of ultrasound may be indicated, in order to avoid the need for repeated catheterization. Consistent residual volumes of more than 200 ml should prompt consideration of whether the patient should be referred for further evaluation.

7.19.6.3 Pad Test for Stress Incontinence

The second diagnostic modification of the prompted voiding run-in protocol is designed to evaluate signs of stress incontinence. Although the presence or absence of stress incontinence does not predict responsiveness to prompted voiding, this diagnostic measure is helpful in cases of residents who fail a trial of prompted voiding and who are candidates for other therapeutic interventions for stress incontinence. This test can be performed during the same toileting episodes in which a clean urine and postvoid residual are being obtained. It is performed by having the resident cough several times while standing. The test is positive if there is urine leakage simultaneous with the cough. If the test is negative and if the total bladder volume (voided volume plus residual) is less than 200 ml, the test should be repeated since a low bladder volume can cause a false negative result. In many cases, it is impossible to obtain an adequate stress test because of either low bladder volumes due to involuntary bladder contraction, low toileting frequency, or difficulty following instructions. Attempts to obtain a stress test should be terminated if it cannot be completed successfully during the first few toileting episodes.

7.19.6.4 Mobility Assessment

The third modification to the prompted voiding protocol evaluates the resident's mobility skills to toilet independently and to do so safely. Two critical questions are addressed by this assessment: (i) will a resident require ongoing prompted voiding management because of physical inability to safely toilet? and (ii) should a resident be placed on a rehabilitation program to improve mobility skills related to toileting?

The extent to which a resident can safely perform the mobility tasks involved in toileting can be evaluated most efficiently during the prompted voiding episodes, during which the resident must move for either changing or toileting assistance. This offers a time-efficient and natural opportunity to evaluate the resident's ability to perform three critical skills for independent toileting: standing, moving (either walking or wheeling a wheelchair) to the toilet, and transferring. A standardized behavioral assessment protocol has been designed to assess these skills (Schnelle, MacRae, Ouslander, Simmons, & Nitta, 1995). The instructions and prompting provided to the resident during this protocol are specifically designed to elicit the maximum possible independent effort. A resident is determined to be capable of independent toileting if he or she performs all three of the tasks either when instructed to do so or with instructions plus gentle manual guidance. Research conducted by the present author has demonstrated that 30–40% of nursing home residents are capable of independently performing all three skills necessary for independent toileting. However, many of these otherwise independent residents can complete these tasks only with major effort, due to deconditioning, muscular weakness, and balance problems, which place them at higher risk for falls. Many of the residents are aware of their safety risk and are so afraid to fall that they do not attempt to toilet independently because of this fear (Schnelle et al., 1994). These residents are candidates for further treatment of mobility problems, and it is anticipated that an unknown percentage of these residents may become capable of independent toileting. Mobility interventions that have been found to have positive outcomes for this group are described in Section 7.19.6.6.

The many residents who are not capable of toileting independently and who cannot be taught to do so safely will have to be maintained on prompted voiding indefinitely so as to receive toileting assistance even if other treatments for UI are attempted and successful. For example, even if a resident is capable of maintaining dryness for several hours at a time due to an intervention such as drug therapy, this resident will only be continent to the extent that staff offer him or her an opportunity to toilet on a regular basis.

Similarly, even residents who are capable of performing all toileting tasks independently must be maintained on prompted voiding if they are either very slow or show poor strength and endurance. Findings indicate that the average time it takes an incontinent resident to stand is six seconds; the average time span during which incontinent residents can sustain walking in a standardized endurance test is 2.6 minutes (Schnelle et al., 1994). These mobility problems limit the ability to stay dry, and the muscle weakness associated with the slowness and poor endurance place the resident at risk for falling. Thus, many such residents will have to be maintained on prompted voiding so that toileting assistance can be provided for the purpose of getting the residents to the bathroom quickly and safely. The issues involved in the maintenance of prompted voiding are complex and require an effective quality assurance system (described in Section 7.19.6.7). However, a decision regarding whether further evaluation is to be done should be made prior to determining if residents are to be managed on an ongoing basis with prompted voiding. The issue of who are candidates for further evaluation is discussed next.

7.19.6.5 Who are Candidates for Further Evaluation?

Urologic and/or urodynamic evaluation should be considered for residents with sterile hematuria or high (> 200 ml) postvoid residual volumes. Only residents who are candidates for specific interventions based on the results of these evaluations should be referred. Further evaluation may also be indicated for those residents who show positive stress symptoms or high wetness frequencies (two or more times per day), despite attempts to toilet two or more times a day. In these cases, either a stress or urge diagnosis is suspected, and the treatment options available for these conditions (described in Section 7.19.3) could be attempted. Given their attempts to toilet, these residents clearly have demonstrated at least the minimal cognitive capacity and motivation necessary to be appropriate candidates for these types of treatment. Recommendations for treatment with alternative behavioral, surgical, or pharmacological interventions should be qualified by the fact that there is no strong evidence that such interventions are successful, even with carefully targeted nursing home residents.

Further evaluation by a physical therapist is recommended for residents who either cannot independently perform all three mobility skills related to toileting or who do so very poorly and who are felt to have some potential for improving these skills. Based on previous work, we estimate that most incontinent residents will be in need of either a physical therapist consultation or a rehabilitative nursing exercise program designed to improve mobility, endurance, and muscle strength. Moreover, as discussed in Section 7.19.2, we reviewed data which indicates that UI and immobility problems are jointly predictive of a high rate of infection and hospitalization to treat these infections. An intervention program that addresses both risk factors is needed, even if the resident cannot attain toileting independence because of reversible physical or cognitive problems, since such a program may also prevent infections. Mobility interventions that may be effective with incontinent nursing home residents are now described.

7.19.6.6 Treatment for Mobility Problems that Limit Independent Toileting

It is not known to what degree physical therapy assessment and treatment is appropriate for incontinent nursing home residents who are chronically ill, demented, and who require maximal assistance to perform the three mobility skills related to independent toileting. Two separate exercise rehabilitation trials, each lasting for nine-week periods, have not been successful in significantly improving the independence level of these very dependent residents (Schnelle, MacRae et al., 1995). However, improvements have been found in endurance, speed, and safety levels for all three mobility skills among residents capable of performing these skills independently or with minimal physical assistance (Schnelle et al., 1996; Schnelle, MacRae et al., 1995). These findings are a result of a mobility intervention utilizing a functional incidental training (FIT) technique.

FIT is implemented concurrently with prompted voiding and involves two primary additions. The two additional FIT steps are done each time prompted voiding occurs when the resident is out of bed. First, the resident is encouraged to perform the toileting-related activities with minimal staff assistance. This is in contrast to standard care since, as a result of staff time constraints, aides typically provide maximal assistance to the residents in completing the prompted voiding sequence. In the absence of functional considerations, it is more efficient to provide such maximal assistance and to minimize the resident's involvement; however, the FIT intervention promotes functional activity. In the second FIT step, the resident is given repeated practice in each functional activity (e.g., standing, moving, transferring) and works toward an individualized goal, which is increased progressively as the resident demonstrates improvement.

The application of the FIT protocol three times per day for nine weeks has been shown in a controlled trial to result in significant improvements in walking endurance, standing speed, wheelchair endurance, and safety measures for a group of 38 residents (Schnelle, MacRae et al., 1995). Unfortunately, only 10% of the residents showed improvement on these mobility tasks to the point where they were rated as being at a low risk for falls. A modification of the FIT protocol is currently being tested which includes resistance training designed to further improve muscle strength. There is strong evidence from several trials that even very old nursing home residents will show strength improvements with resistance training (Fiatarone et al., 1994; Mulrow, Gerety, Kanten, & Cornell, 1994). In addition, FIT is being implemented for longer time periods to explore further its potential for producing a higher level of mobility independence and a lower risk for injury and infections which may require hospitalization.

However, even if these mobility interventions are successful, most residents will require routine prompting and some physical assistance to maintain continence and to maintain their improved mobility performance. A quality assurance system to assure that staff continue to provide such assistance is critical; therefore, the behavioral management skills that staff must learn to successfully implement such a system are discussed next. This behavioral management involves a system of accurately monitoring the resident incontinence status. It is in this critical arena that the role of the behavioral psychologist is most needed.

7.19.6.7 Staff Management and Continence Maintenance

Three major issues must be addressed if toileting assistance and the continence maintenance aspects of the prompted voiding program are to be accomplished. These issues, although discussed here specifically with regard to prompted voiding, are essential to any intervention requiring caregiver assistance. First, procedures are needed to target those residents who will respond well if ongoing toileting assistance is provided. Second, an information system must be developed to monitor incontinence outcomes effectively so as to facilitate quality control. Third, supervisors and direct care staff who actually implement the prompted voiding protocol must be taught how to use the outcome data to identify and correct problems. A comprehensive description of how these issues must be addressed to facilitate the implementation of prompted voiding can be found in several places (Ouslander & Schnelle, 1993; Schnelle, Ouslander, Osterwell, & Blumenthal, 1993).

The methodology to target residents who can be responsive to the prompted voiding toileting program has been described earlier in this chapter; specifically a three-day run-in assessment is described for this purpose. This same three-day assessment also provides the outcome data needed to maintain the incontinence system effectively. In review, during this three-day period residents are checked for wetness and prompted every two hours. Those residents who have a 66% appropriate toileting ratio or better are designated as responsive and are recommended for ongoing maintenance. The wetness data from these responsive residents collected during the two-hour checks can now be used to generate a control chart, which is the basic information tool used to monitor the prompted voiding program, thereby addressing the need for effective quality control (Fogarty, Schnelle, & Newman, 1989; Schnelle, Newman, Fogarty, Wallston, & Ory, 1991).

A control chart is a graphic display that allows the viewer visually to ascertain expected versus actual outcomes (Figure 2). The control chart in this case is constructed by graphing wetness data collected during each two-hour block during the three-day run-in period and calculating the average and standard deviation of this wetness. A warning limit is set two standard deviations above the average. This warning limit signifies unexpected variability and indicates either a failure of the prompted voiding work process to be implemented consistently or, perhaps, a change in the resident's status. For example, the control chart shown in Figure 2 was generated for a group of 22 residents. This control chart shows that 12% of the residents who showed $\geqslant 66\%$ appropriate toileting rate during the three-day assessment period were found wet on the two-hour checks. A warning limit was set above this 12% average at 40%. This warning limit is two standard deviations above the average. An upper warning limit is established three standard deviations above the average. Supervisory nurses and direct care staff can now effectively monitor the prompted voiding program by randomly checking at least 10 residents per week for wetness. If the findings of this check, termed a control check, are within the average and two standard deviations of the expected average, the prompted voiding system can be said to be in control. If the wetness rate for the 10 patients exceeds the warning limit, then an analysis should be done to identify the causes of this excessive variability. A failure of staff to implement the prompted voiding program consistently or a deterioration in a resident's status are two potential explanations for an unusually high wetness check.

Software has been developed to facilitate the analysis and interpretation of the control checks, and supervisory and direct care staff have been taught how to use the software to identify problems and to provide feedback to the staff who are implementing prompted voiding. The implementation of this computerized system has resulted in successful maintenance of high levels of resident dryness during six-month to one-year evaluation periods in eight nursing homes (Schnelle, McNees, Crooks, & Ouslander, 1995). The failure of more traditional employee training methods to sustain such improvements have been described in several places (Schnelle, Newman, & Fogarty, 1990a). Unfortunately, the staff training and management interventions that have been evaluated have only been successful as long as research staff were present to provide support and social incentives to both supervisory and direct care staff to maintain the system.

The fact that maintaining resident dryness with a toileting program is more time consuming than simply changing residents when they are wet produces strong natural pressures that reduce staff motivation to maintain the program. The development of incentives to increase the motivation of nursing home staff to implement the more labor intense toileting program is an important new area to be investigated, and this is discussed in the next section.

7.19.7 FUTURE DIRECTIONS

Numerous areas related to incontinence treatment that are in need of research can be identified for both community dwelling and nursing home populations. Furthermore, many of these areas have direct relevance to behavioral scientists. For example, in the case of community dwelling populations major questions remain as to why most people with incontinence symptoms do not seek treatment. Behavioral interventions to increase people's willingness to be treated could possibly be developed if such information were available. Furthermore, such interventions to increase people's awareness of treatment options are clearly justified by the evidence that urinary incontinence is predictive of general functional decline in the community dwelling elderly. The fact that urinary incontinence is associated with a decline in measures of emotional functioning in the community dwelling elderly is also an area of interest for future behavioral research (Tinetti et al., 1995).

In the case of nursing home residents, major improvements have been made with incontinence problems by utilizing the assessment, treatment, and staff management system described in this chapter. In addition, the work to date suggests future research directions that should lead to further improvements in how incontinence care might be done in nursing homes. Two of these most important future directions have direct implications for behavioral scientists.

The first issue relates to the development of incentives that will motivate staff to maintain the quality control and information feedback system that is so critical to the maintenance of the prompted voiding program. The reality that maintaining continence is more time consuming than simply changing residents when they are wet contributes to the maintenance problem. However, the fact that even residents who are responsive to the prompted voiding program are not good self-advocates because of high sickness burden, dementia, or other unknown factors has not been discussed, and makes the need for incentives even more imperative. Unfortunately, most residents do not provide sufficient positive verbal feedback to nursing home staff when they provide toileting assistance so as to maintain the more labor intense toileting activities, and many residents can be convinced that they should accept their incontinence condition and a changing schedule as opposed to a prompting and toileting schedule.

Several approaches could be taken in reaction to this problem. First, external incentives that link the maintenance of the prompted voiding protocol to job advancement or salary increases could be attempted. These reinforcement strategies have been used successfully with other institutional populations that are not good self-advocates or are incapable of socially reinforcing staff for better care. A description of this behavioral research is available (Burgio & Burgio, 1990; Burgio et al., 1990).

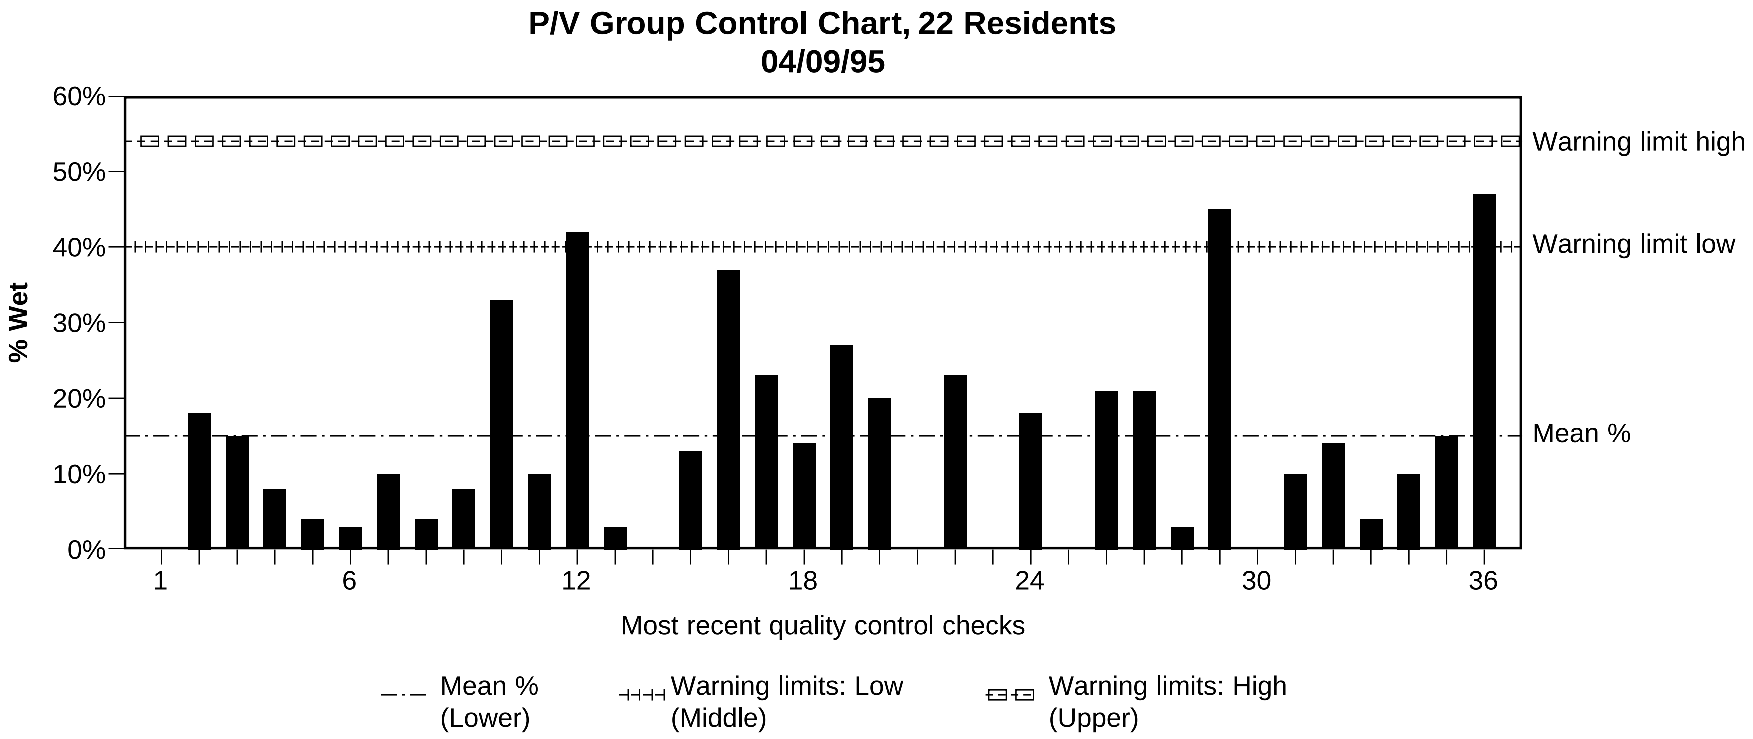

Figure 2 Sample control chart.

A second approach would be to develop interventions designed to make either residents or their families better advocates for their own care. With this approach, families and residents would have to be taught how to recognize good incontinence care and to interact with nursing staff in a manner so as to reinforce good care when it occurs. This form of patient/family involvement has been discussed by several consumer groups, but there have been no examples where this type of intervention has been done successfully.

A second direction for future behavioral research is related to the motivation of residents to be continent. The fact that many residents (estimated 15–30%) react negatively to the prompted voiding procedures and appear to prefer to be changed as opposed to toileted has been discussed previously in this chapter. These residents are not even carried into the staff management phase of the prompted voiding program because of their unresponsiveness to the prompting procedure during the run-in evaluation period. Research to measure residents' preferences for care and to determine the factors that contribute to these preferences would be important innovations that could guide how incontinence care should be delivered. For example, are preferences to urinate in pads and be changed as opposed to toileted influenced by the residents' reduced expectations of what is possible in the nursing home, or by true preferences for changing because it is less bothersome or painful than the toileting sequence? There are reasons to believe that both hypotheses may be plausible. The fact that many residents have experienced incontinence symptoms that were untreated before they entered the nursing home has been discussed in earlier sections in this chapter. It is thus plausible to predict that many residents may have adapted to the condition and sincerely are no longer bothered by wetness. Alternatively, it is also plausible to predict that some residents may have been convinced by nursing home staff that they should accept their incontinence condition because staff do not have time to help with toileting and thus have resigned themselves to the condition. Preferences based on the patient's acceptance and adaption to the condition versus preferences created by nursing home staff persuasion would require different interventions. In the first case it is arguable if anything should be done to convince residents of their need to be concerned about toileting, whereas in the second case an intervention to reverse the dependency and low expectations about care created by nursing staff is certainly necessary. Unfortunately, we know almost nothing about how to assess accurately the preferences of demented nursing home residents. The development of such a technology will allow us to begin the process of truly individualizing resident care according to their needs, not only in the case of incontinence care but also in other care areas.

7.20.1 INTRODUCTION

Community-based mental health services assist older adults with serious psychological disorders who have been moved out of institutional care facilities, as well as seeking to prevent older adults with such disorders from entering institutional care. In addition, community-based services assist older adults with acute psychological distress who are not at risk of placement in institutions. In this chapter, we describe community-based mental health services in the United Kingdom and the United States, we highlight similarities and differences, and we explore the historical and political–economic contexts that shaped these service systems.

7.20.2 MULTIPLE SYSTEMS OF MULTILEVEL CARE

The notion that community-based services for older adults with mental illness form one coordinated system is not a sufficient description. Knight (1991; Knight & Kaskie, 1995) argued that older adults with mental health problems are embedded in a variety of distinct care systems at both institutional and community-based levels: mental health systems, medical care services, long-term care for the elderly, and aging network services. Our understanding of community-based mental health services necessitates a systems level analysis where each system is considered independently and in relation to each other. This systems analysis departs from the more typical "coordination of services" and "gaps in the system" arguments in four distinct ways.

First, we contend that systems of care operate on different principles and create a legitimately confusing service world for both the older client and the professional service provider. Gaps in service provision exist because different systems were created for different purposes (mental health treatment, medical care, or social support). These systems have developed in response to different historical pressures rather than because someone overlooked elements while rationally laying out a system for older adults.

Second, failures to coordinate are more often dictated by economic pressures than by muddled planning or by providers' personal failings. Economic resources for mental health services are scarce and have become even more meager since the Reagan–Thatcher era of tax cuts and cost reductions to public services. Older people, especially those who need mental health services, continue to suffer from the "last-in, first-out" principle. In the UK, financial pressures and the increasing costs of acute medicine have drawn health services funding away from the chronic problems typical of those faced by older adults. In the US, support for older adults' mental health services by the Carter administration was rescinded by Reagan era cutbacks. Older adult services receive a minimal amount of funding, and continue to be subjected to further cutbacks. With such severely limited resources, the economic pressure is for systems to compete rather than to cooperate.

Third, service use is further complicated because older adults experience coexisting physical health and/or social difficulties, making it all too easy for each system to displace responsibility to another "more appropriate" system of care. A system may limit service delivery to existing clients and may not accept clients who "belong" to some other system. Further, limited financial support may cause a system to not provide adequate care even to those older adults who "belong" to the system. As noted by Gatz and Smyer (1992, p. 744), "everyone and no one is responsible for the clients." Indeed, the task of assuring appropriate community-based care for older adults with mental health problems becomes one of securing appropriate services from multiple competing systems, each of which has distinctive operating principles and incentives to provide services.

Fourth, the delivery of community-based services is further complicated by the fact that the different systems do not share the same definition of "community." For example, Knight and Lower-Walker (1985) noted that the mental health system moved older adults into nursing homes, which it defined as a transition from state hospital care to "the community." The aging network in the US has, in marked contrast, tended to define nursing homes as the prototypical institution from which older adults must be moved "to the community."

Our objective is to place the provision of mental health services for older adults in the context of the multilevel mental health services system as well as within other systems of care: long-term care, medical health care, and social services. In what follows, we begin with the long-term hospitals for older adults with mental disorders which are the historical antecedents of community care. The remainder of the chapter will consider community-based interventions.

7.20.3 THE STATUS QUO ANTE: LONG-TERM INSTITUTIONAL PSYCHIATRIC CARE

In the UK, county asylums emerged from the seventeenth and eighteenth century workhouses and institutions of confinement which were common throughout industrial–urban Europe (Foucault, 1965). The nineteenth century saw the development of psychiatry and the redefinition of these institutions as places for treatment of the insane (Foucault, 1965). Many county asylums became large institutions with several thousand inmates. Arie and Jolley (1982) commented that in the mid-1970s half of all asylums were occupied by people over 65, reflecting that:

> Mental hospitals which were built to provide asylum for the mentally ill before more active treatments were available, are nowadays increasingly occupied by old people whose numbers would grow even further were it not for enforced government rationing and not uncommon reluctance on the part of psychiatrists to admit them. (Arie & Jolley, 1982, p. 225)

Institutional psychiatric care developed in the US in the late nineteenth century as a humane alternative to imprisonment, to mistreatment in family homes, and to vagabond status for the mentally ill (Rosen, Pancake, & Rickards, 1995). The US had a shorter, less urban–industrial history, and so institutional care emerged as an alternative to no care rather than a redefining of existing institutions. Older adults were often over-represented in US inpatient psychiatric institutions in comparison to their representation in the general population. Between 1910 and 1950, for example, the state and county psychiatric hospital network expanded substantially in the US and admissions of older adults doubled (Grob, 1987; Rosen et al., 1995). Adults over the age of 65 represented 25% of the total patient population, and state and county psychiatric hospitals were the principal points of care for a population with an assortment of diagnostic, economic, and social attributes (American Psychiatric Association, 1993).

7.20.3.1 Deinstitutionalization of Mentally Ill

In the UK, the move to close large psychiatric institutions and replace them with local, community-based services began with the development of acute psychiatric units which were attached to local general hospitals during the 1960s and 1970s. The continued closure of mental hospitals was underpinned by rhetoric regarding the benefits of community-based care and driven by several Public Inquiry Reports of the scandalously poor conditions existing in such institutions. There were clear financial incentives also. The cost of maintaining and refurbishing the hospitals was growing and they became increasingly inefficient to operate with the falling number of patients. Also, there was an opportunity during the 1980s to transfer financial responsibility for patients from health budgets to the social security budget, through the transinstutionalization of patients from asylums to residential and nursing homes.

The movement of younger patients into the community led to older people forming an increasing proportion of the mental hospital population. Yet, the development of age-appropriate services varied greatly from area to area, often depending on the presence of a charismatic psychiatrist. By 1986, about 70% of the UK population had access to a specialist psychiatrist in old age mental health care (Ineichen, 1989) and developments have subsequently continued. This growth has helped to focus attention on the inadequacy of mental hospitals for older people with dementia or other mental health problems.

Beginning in 1955, older Americans were included in the mass "deinstitutionalization" of psychiatric patients from state hospitals to the community. Publicly supported psychiatric hospitals began an extended process of transferring older patients to the community (i.e., deinstitutionalization) or to other facilities such as nursing homes (i.e., transinstitutionalization). Moreover, state and county psychiatric hospitals applied more stringent admission criteria that reduced older adult admissions altogether (Kahn, 1975). This movement is generally attributed to the discovery of more effective psychopharmacological interventions and to a desire to provide more humane care in the least restrictive setting (Rosen et al., 1995), although cost control undoubtedly played a part. Hospitals were full and state legislatures were faced with the choice of building more or doing something else (Rounds, 1984). Moak and Fisher (1991) reported that 96% of the state hospitals had a floor, unit, or wing designated for geriatric patients. Yet, just 60% of the state hospitals retained a professional staff member who was trained in geriatric psychiatry and less than 20% of the hospitals provided any form of psychosocial treatment. These findings support the American Psychiatric Association's (1993) position that state and county hospitals rely on psychotropic medications and rarely use psychosocial interventions—even though well-designed, multidisciplinary treatment principles have been formulated.

7.20.3.2 Do The Old Institutions Still Exist?

The care of older adults who reside within institutional settings has changed. The image that county asylums and state hospitals provide only chronic, custodial care is contradicted by recent studies. In the areas of the UK where final closure has yet to occur, older patients are likely to be admitted to specialist inpatient assessment and rehabilitation units with a very few continuing care beds. Most of the long-term care admissions occur in areas where the independent sector has been slow to develop nursing home alternatives (Tomenson, Benbow, & Jolley, 1994; Wattis & Fairbairn, 1996).

In the US, Clark and Travis (1994) reported that just 20% of their older adult sample remained in the hospital for more than one year, while most of the rest were discharged. At least 15% of these older patients returned to the community while the remainder were released to another community-based facility such as a foster home, board and care facility, or nursing home (10% died in the hospital).

7.20.3.3 Who Was Discharged from Psychiatric Institutions?

In the UK, the older people affected by the closure of county asylums fit into two principal groups: (i) Chronic patients, usually with a long history of psychosis and having been hospitalized for many years. Arie and Jolley (1982) estimated they formed approximately 20% of the mental hospital population. They have often been discharged to hostels, residential and nursing homes (e.g., Dean, Briggs, & Lindesay, 1993). Anderson and Trieman (1995) suggested that over half this group may additionally have a moderate to severe degree of cognitive impairment. (ii) People with severe dementia—usually admitted because of behavioral problems and mainly discharged to nursing homes (e.g., Lyons, Cohen, Henderson, & Walker, 1995). In some cases, they are discharged to homes that are specially designed for people with dementia, for example, domus homes (Dean et al. 1993; Lindesay, Briggs, Lawes, MacDonald, & Herzberg, 1991; Skea & Lindesay 1996). These are small, "homely" living units, with specially trained staff and a philosophy encouraging attention to psychosocial aspects of care, to balance the traditional emphasis on physical care.

Based on the 1994 State and County Mental Hospital Inpatient Survey, Semke, Fisher, Goldman, and Hirad (1996) suggested that the US state hospital population could be sorted into three prominent groups: older adults with schizophrenia comprise 40.2% of the population, older adults with dementia total 30.0%, and those with depression and other late-onset disorders account for 13.1% of elderly patients. Another 10% were diagnosed with alcoholism, mental retardation, and other psychoses.

In summary, the image of county asylums and state hospitals as custodial warehouses where older patients are admitted and abandoned appears to be out of date. Rather, most hospitals provide limited inpatient services to older adults who are placed back to the community or another facility within a year of admission. In some places, the state or county hospital may be the only point of inpatient service. In considering policies surrounding community care, it is important to recognize that the county asylum and state hospital systems have changed dramatically. These hospitals have emerged as a form of community-based care, especially for older adults affected by psychoses, dementia, and severe affective disorders.

7.20.4 ACUTE PSYCHIATRIC INPATIENT SERVICES

In the UK, many districts have an inpatient old age psychiatry assessment unit on a general hospital site, with varying degrees of collaboration with geriatric medicine units (see Arie & Jolley, 1982; Ineichen, 1989). Typically, these are the central component of a community-based service for older people. Some of these inpatient units provide separately for those presumed to have dementia and those with an affective disorder. The advantages of having the inpatient unit on a general hospital site include increased access to the general hospital, access to specialists for coexisting physical health problems which might complicate the person's presenting state and course, and the opportunity to develop liaison services between mental health and general medical wards.

Over the last 20 years in the US, adult psychiatric inpatients have moved from state and county facilities, and now predominantly use general medical and private psychiatric inpatient hospitals (Kiesler, 1991). Narrow, Regier, Rae, Manderscheid, and Locke (1993) reported that 43.3% of all adult inpatients were admitted to either a general hospital psychiatric unit or scatter bed ("scatter bed" refers to individuals who are admitted to a hospital that does not have a special psychiatric unit or department), while 10.8% were admitted to a private psychiatric hospital. Atay, Whitkin, and Manderscheid (1995) examined the Inventory of Mental Health Organizations survey and, after excluding those older adults who resided in nursing homes, found that 21.6% of all elderly inpatients were treated in general hospitals, and 10.6% were treated in psychiatric hospitals. The remainder were treated in state or county hospitals, Veteran's Administration Hospitals, or by inpatient services affiliated with multiservice community mental health centers.

7.20.4.1 Who is Served in Geropsychiatric Inpatient Units?

Are these the psychotic and demented elderly who were the principal patient populations of state hospitals? Reports from individual hospital programs suggest that this may not be the case. In the UK, Domken, Bothwell, and McKeith (1995) analyzed discharge data from a well-established old age psychiatry unit. Comparison of the years 1985, 1988, and 1991 illustrated the growth in discharges to independent sector homes, together with increased admission rates and shorter lengths of stay. The proportion of patients having a functional disorder without organic impairment fell from 50% in 1985 to 25% in 1991, reflecting increasing reliance on day-hospital and community support for the functional disorders group.

In the US, Conwell, Nelson, Kim, and Mazure (1989) found that of 168 consecutively admitted patients to a geriatric inpatient unit in New Haven, 75% were diagnosed with an affective disorder and 25% with dementia. Knight and Carter (1990) reported that most geriatric admissions to a psychiatric inpatient unit in southern California were diagnosed with psychoses (47%) or with affective disorders (36%), with about 14% diagnosed with an "organic brain syndrome."

In summary, the role of acute psychiatric inpatient care has been overlooked when discussing community-based services, reflecting a tendency to equate inpatient care with custodial institutional care. However, impatient treatment of mentally disordered elderly appears successful using both psychopharmacologic (Schneider, 1995) and psychosocial (Gatz, Popkin, Pino, & VandenBos, 1985) interventions. Moreover, Knight (1983, 1986) reported that the utilization rates of inpatient and outpatient care by older adults in the counties of California were statistically independent of one another, suggesting that the systems serve different community-based populations. Short-term inpatient care close to home appears in fact, to be an important and distinct component of community-based care for older adults.

7.20.5 MENTALLY ILL OLDER ADULTS IN NURSING HOME CARE

In the UK, around 5% of older adults live in permanent institutional care. The majority (approximately 72%) of these older adults in 24 hour care live in residential or nursing homes which are not provided by the National Health Service (NHS), housing authority, or by local government. Many of these people are funded, at least in part, by a combination of Social Services and Social Security payments. The high prevalence of psychiatric morbidity in residential homes in the UK is well established. For example, Neville et al. (1995) assessed older people in four local authority residential homes. The great majority (82%) had some degree of dementia. Over half (53%) of the residents were assessed as having severe dementia. Of those (45%) able to complete a self-report depression scale, 17% scored in the depressed range. Of the whole sample, only 17% showed no evidence of dementia or depression. The rate of depression reported here is much lower than in previous studies (see Ames, 1991), where over a third of residents without severe dementia have been depressed.

The lower prevalence of depressed older adults in residential care may be due to improved assessment as well as more creative community treatment and support packages which enable older people with depression to remain in their own homes. An alternative hypothesis would be that the closure of hospital beds for severe dementia places pressure on local authority homes to accept a greater number of people with severe dementia, while independent sector nursing and residential homes—who have more choice over which residents to accept—absorb the less physically dependent and behaviorally disturbed group of depressed older adults. This illustrates the need to examine trends across the multiple systems (health, mental health, social) of institutional care. Examining one component in isolation gives an incomplete, and perhaps misleading, picture.

In the UK, the National Health Service and Community Care Act (1990) was motivated by the need to control the flow of resources into residential and nursing homes; previously, funding had been available without assessment of need. Although wrapped in rhetoric about providing better community support and services, assessments of need form the basis for targeting the provision of institutional care (see Gilleard, 1996a). "Need" for continuing hospital care is more likely to depend on availability than on any rational assessment; some districts have very few hospital beds, others retain a significant number (Tomenson et al. 1994).

Between 1963 and 1990, nursing homes expanded tremendously in the US from 445 000 to 1 772 000 individual beds as Medicare and Medicaid were initiated and included financial support for long-term care services (Darney, 1994; Schick & Schick, 1994). Moreover, the nursing home population grew as patients were supplied by the transinstitutionalization of older adults from state psychiatric hospitals (Kahn, 1975), a move which represented a cost-cutting strategy for state legislatures who moved the elderly mentally ill from totally state-funded psychiatric hospitals to partly federally-funded nursing homes (Estes, 1995).

In 1963, 48% of institutionalized mentally ill elderly were in state psychiatric hospitals with the remainder in nursing homes; in 1969, 75% were in nursing homes (Dorwart & Epstein, 1993). The nursing home setting would appear to be where many of the former psychiatric hospital population would now receive care: 50% of nursing home residents are demented, 30% have psychoses (Shadish, 1989).

More recently, the US Federal Government responded to the relocation of older mentally ill with the Nursing Home Act of 1987. This act recognized that older adults with psychiatric conditions were over-represented in nursing homes and stipulated that nursing homes must screen patients for psychiatric illness. If patients were diagnosed with a mental illness, then the nursing home was required to (i) provide appropriate psychiatric care, or (ii) deny admission to them and/or transfer them to a more appropriate facility (Smyer, 1989). Smyer, Shea, and Streit (1994) reported that at the time of the passage of this law, 65% of older adults in nursing homes who had mental health problems did not receive treatment for these problems. They also reported that for-profit homes tended to rely on bachelor's level counselors and government homes used psychiatrists, whereas private nonprofit homes used psychologists and social workers as well as psychiatrists. Early estimates suggested that between 2.4% and 18% of residents would be excluded from nursing home care by this act (Freiman, Arons, Goldman & Burns, 1990; Eichmann, Griffin, Lyons, Larson, & Finkel, 1992). However, later reports suggest sharp increases in mental health service provision in nursing homes after the passage of this law (Knight & Kaskie, 1995; Office of Inspector General, 1996), rather than discharges of patients with mental health problems. However, there are concerns about service standards and fraud: approximately 24% of Medicare billings in 1993 for mental health services to nursing home residents were estimated to be medically unnecessary (Office of Inspector General, 1996). Two-fifths of the insurance carriers for the Medicare program considered part of the problem to be "excessive entrepreneurialism" on the part of mental health professionals (Office of Inspector General, 1996, p. 13).

On the whole, the issue of providing adequate treatment to the transinstitutionalized older mentally ill resident of nursing homes in the US is still unresolved. For these individuals, "return to the community" has meant a shift from the mental health system to the long-term care system, reduced access to mental health treatment, a shift of care from the states to private sector institutions, and a shift of costs from states to a mix of federal-state (Medicaid) and private (patient and family) financing.

Lomranz and Bar-Tur (see Chapter 21, this volume) provide more comprehensive coverage of the nursing home population and service models for mental health treatment. Our point is that many, probably most, of those moved to "the community" were transferred to nursing homes from state hospitals, and that long-term psychiatric hospital treatment and care has been replaced by such homes in both the US and UK. In the remainder of this chapter, we explore community-based outpatient mental health services for older adults.

7.20.6 OLDER ADULTS IN COMMUNITY MENTAL HEALTH SERVICES

In this section, we cover the provision of mental health services to older adults outside of 24-hour care institutional environments. The range of services and settings described includes traditional and nontraditional outpatient services, partial hospitalization and related day care services, respite care, and support for caregivers.

7.20.6.1 Community-based Mental Health Outpatient Care in the UK

All community-based services in the UK operate in the context of Department of Social Services community care assessment and care management, intended to ensure that needs are properly assessed and that service provisions are targeted appropriately. Challis (1992) reviewed good models of providing community care through care management schemes. Some success is reported with mental health problems as well as with physical frailty. They have tended to include older people with dementia, rather than to focus specifically on them. Although apparently intended to be the basis of UK community care provision, important elements of the demonstration programs have often not been present in mainstream practice. The key elements included a high degree of flexibility, an available budget per person to "buy in" services, availability of paid volunteers, and a skilled assessment of need. There is widespread disappointment with the very basic packages of care being offered, and there is concern to ensure that specialist mental health services are involved more fully in assessment and care planning (Department of Health, 1996).

7.20.6.1.1 Multidisciplinary teams

The key element of such specialist community services in most areas of the UK would be a multidisciplinary team (MDT) usually seeing the older person in his/her own home. Most teams aim to respond quickly—within a few days—to referrals, more rapidly for urgent cases. The range of disciplines involved varies greatly; at a minimum, most members may be community psychiatric nurses, perhaps with an old age psychiatrist having a part-time input to the team. Elsewhere, occupational therapists, physiotherapists, social workers, speech therapists, clinical psychologists, and workers from voluntary agencies for older people may be team members. Typically the teams have been established by redirecting resources from mental health hospital provision; most teams liaise closely with inpatient old age psychiatry units and day hospitals. Often the team will share a hospital base with these services, although increasingly efforts are being made to locate such teams more accessibly, for example, in primary health care centers.

Most teams have a defined population to serve, and will usually see clients referred from residential and nursing homes within this area, as well as those living at home (Brown, Challis, & von Abendorff, 1996). Many teams will accept referrals from any agency, or from families or self-referrals; other teams maintain the traditional, less accessible, stance of only accepting referrals from the person's primary care physician. Some teams insist that all referrals are seen by a medical member of the team; others have a policy that a team member from any discipline may carry out the initial assessment meeting, where medical input would be available.

Coles, von Abendorff, and Herzberg (1991) evaluated the initial impact of a new community mental health team in an Inner London borough. This service replaced a traditional hospital-based system in which a consultant psychiatrist made domiciliary visits. The new community team was multidisciplinary, and used a keyworker scheme, where one member of the team would be allocated primary responsibility for the coordination and delivery of the service provided to each case. In a period of six months the team assessed over 90 more referrals than the consultant had seen in the equivalent period. The primary diagnosis for both the MDT and the consultant was dementia, which made up approximately 40% of all referrals. Depressive disorder accounted for 30.3% of diagnoses by the MDT and 18.3% of diagnoses by the consultant. The team was able to provide increased levels of input including treatment for depression, coordinating a range of services, and counseling and support for caregivers.

Junaid and Bruce (1994) investigated the effectiveness of community psychiatric nurse services for the elderly in a particular district. They found wide variation in the numbers employed per thousand people over 65 (from one per 2255 to one per 9200; The Royal College of Psychiatrists recommends one nurse per 5000 of the population over 65). They found large differences in the skill mix of the community teams. In some teams nurses would specialize in patients with specific diagnoses, for example, cognitive impairment, neurosis, or psychosis. Other teams would share case loads equally. In conclusion, Junaid and Bruce stated "Current provision appears to be based primarily on historical trends of resource allocation, and also on a varying commitment to community development which is evident in the philosophy or approach of the teams" (p. 718). It would seem that while the development of MDTs may have led to an improvement in services at a local level, the variation among teams' working practices and funding allocations has led to wide regional and inter-regional differences.

In the UK, some mental health teams (see Dening, 1992) specialize exclusively in working with people with dementia, whereas others cover all mental health problems of older people. Brown et al. (1996) provide details of referrals, caseloads, contact history, and outcomes of two well-established and pioneering teams which work with both organic and functional disorders. They took a random sample of 120 open cases on caseloads of two MDTs for elderly people, both with an open access policy, and followed up these cases over an 18-month follow-up. The teams' caseloads contained a greater proportion of patients with affective disorders, and less with dementia, in comparison with referrals to the team. The response to dementia appeared to be a briefer episode of contact, emphasizing assessment and diagnosis more than continuing support. A higher proportion of those with affective disorders remained at home at follow-up. This tendency for people with dementia and their caregivers to be rapidly discharged from the active caseload has led these teams to explore the use of specific long-term workers attached to the team to act as case managers for people with dementia and their families. Elsewhere, an innovative response has been the development of a specialist mental health nursing service to work specifically with family caregivers (see Woods, 1995), or teams working only with people with dementia, offering assessment, ongoing support, interventions to relieve caregiver strain, and facilitation of appropriate services.

Outcome studies of the work of such teams with people with dementia are yet to be completed. O'Connor, Pollitt, Brook, Reiss, and Roth (1991) have reported a controlled trial of the effect of an MDT on admission rates of people with dementia over the age of 75 over a two-year period. The team offered a wide range of help to people with dementia and their families identified in an ascertainment survey—including advice on and help in arranging services and benefits and respite admissions. No difference in admission rates, compared with control patients, was noted in those living with a caregiver. Those living alone were much more likely to enter residential care than controls. However, this study does not necessarily reflect outcomes in usual practice where the person or their family seeks help, rather than being identified as someone in need, as was the case here. More positive results are reported by Hinchliffe, Hyman, Blizard, and Livingston (1995) in a study where caregivers were offered an intervention devised by an MDT, which included components of behavioral, practical, and pharmacological input depending on the assessed needs of the situation. Caregiver mental health and the patient's behavioral difficulties improved compared with a waiting-list control group.

Although around 10% of the teams' caseload in Brown et al. (1996) had a diagnosis of schizophrenia, it is not clear what proportion of these had developed a psychotic illness such as paraphrenia in late life, as opposed to having a long-standing mental health problem. Generally, patients who have been receiving mental health services for many years are not transferred to old age services when 65, unless these services are more appropriate (e.g., because of the development of a dementia or physical health complications). Little has been documented regarding the effects of this approach.

In summary, community teams have developed widely, with very little in the way of evaluation, or even detailed descriptions of practice, since the early publications (Lindesay, 1991). Their service coordination role has, to an extent, been taken on formally by Social Services through the community care assessment and care planning process, and there are significant differences between areas in the extent to which the skills of the MDTs are utilized in carrying out specialist assessments and planning programs of care for older people with mental health problems. Some teams have very close links with social worker team members, and carry out many community care assessments; others find themselves much less involved, at best acting as an advocate for the patient's service needs. Although diversity of team functioning can be seen as flexibility to respond to local circumstances, the lack of consistency makes it difficult to know whether such teams do offer an effective way of organizing the response to mental health needs of older people in the community. Most teams attract high levels of referrals, and so appear to be meeting a demand, but this is of course an inadequate measure of efficacy. Two further developments—Memory Clinics and Family Therapy Clinics—in the UK are worthy of mention. Although their implementation is not yet as widespread as community teams, they promise to significantly shape the direction of future services.

7.20.6.1.2 Memory clinics

Early diagnosis of memory disorders is regarded as fundamentally important when treating and counseling individuals with dementia. The memory clinics have been developed to provide community-based services to older adults with dementia. All memory clinics provide an outpatient diagnostic assessment, and, in many centers, advice and counseling is offered to the person and their family, along with any appropriate treatment.

The first British memory clinic was established in 1983 at St. Pancras Hospital, London. A recent review of memory clinics in the British Isles (Wright & Lindesay, 1995) identified 20 clinics running in the UK and Ireland. Memory clinics provide diagnostic assessments for dementia and other memory disorders. Typically, patients receive a cognitive assessment involving standardized tests of cognitive functioning (including the Mini Mental State Examination, MMSE; Folstein, Folstein, & McHugh, 1975) and mood. A wide variety of physical investigations are used including full physical examination, computerized tomography scanning, magnetic resonance imaging, and blood tests. On average, around three-quarters of referrals to the clinics were diagnosed as having a dementing condition. Clinics vary in the cognitive tests and physical investigations used. The time taken to carry out full assessments was reported to vary from one to six hours. It is not clear whether the differences in practice have any clinical impact.

The number and type of staff running memory clinics vary. The professionals commonly involved are psychiatrists, geriatricians, neurologists, psychologists, and nurses, as well as speech therapists, social workers, and occupational therapists. Staffing levels vary as does the amount of any specific type of professional input to the service. Many of the memory clinics in the UK are actively involved in recruiting participants for research into dementia and specifically Alzheimer's disease. The research is both pharmaceutical and nondrug orientated.

Memory clinics provide an important service within the communities they serve. They are a useful point of referral for general practitioners, and may provide a starting point for many individuals to find help and information about memory impairment, as well as access to other community services. In a few areas, the follow-up from the clinic is extensive and caregivers receive considerable support over an extended time period (Bayer, Richards, & Phillips, 1990; Gilliard & Wilcock, 1993).

7.20.6.1.3 Family therapy clinics

Family therapy for older adults has only a brief history of implementation in the UK, although old age mental health service providers have long recognized the role of the family as being a significant factor in the psychological and physical well-being of older adults (Colwell & Post, 1959). UK research suggested that family-based work with older adults had useful clinical implications (Ratna & Davies, 1984). However, it is only in the last few years that family therapy for older families has begun to be implemented in practice. Traditionally, families with young children or adolescent members have been the prime focus for family therapy practice. In 1992, Gilleard, Lieberman, and Peeler set up a team for older adults in an established family therapy center in Inner London. The service was underutilized and referrals soon began to "dry up." Research revealed that professionals working with elderly people were unaware of the existence of the team, or had limited knowledge of family therapy with older people in general. Some professionals expressed doubts as to the usefulness of such a service, believing that there was little potential for change in the families of older people. Although misconceptions about older people did have some bearing on the lack of referrals to the new service, practical problems also played a large part. Professionals (especially community nurses and social workers) did not know that they were able to make referrals.

The overwhelming majority of professionals working with elderly people expressed positive attitudes towards family therapy. They suggested ways of making the service more accessible to their particular client groups, by limiting the amount of traveling and by holding all or some of the sessions in the client's home. Altering times of sessions to accommodate working hours was also suggested. By disseminating information regarding the service and by implementing changes suggested by health professionals, family therapy with older adults may become an important resource available to the community.

Research has highlighted the efficacy of family therapy to different elderly client groups (Gilleard, 1996b). Benbow, Marriott, Morley, and Walsh (1993) assessed the usefulness of family therapy with older adults suffering from dementia. The basic therapeutic techniques remained the same as for those older adults with other mental health problems, however, a few differences were found. Family therapy based treatment with dementia patients was often seen in terms of psychological management of the disorder and an increased focus on caregiver stress. Families were crisis-oriented and attended for fewer sessions. These difficulties present new challenges in providing family therapy for dementia sufferers. Continuing development indicates that family therapy with older adults will prove an important addition to older adult mental health services in the UK.

Curiously, family therapy for the elderly has grown slowly in the US. While there are services for caregivers (see Chapter 22, this volume) and well-known advocates for family therapy with the elderly (e.g., Qualls, 1996), there is no effort to establish family clinics as such.

In summary, for the foreseeable future, community MDTs seem likely to form the basis of specialist community mental health services for older people in the UK. Developments which reflect the importance of careful assessment and working with families, such as memory clinics and family therapy clinics, are likely to augment the basic service in some areas, and to influence practice within the teams more broadly.

7.20.6.2 Community Mental Health Outpatient Services in the US

In the US, the Community Mental Health Centers (CMHC) Act of 1963 financed the development of comprehensive community mental health centers. These centers were intended to provide services to the deinstitutionalized mentally ill and to provide services to persons who would have been institutionalized in the past. CMHC services target state hospital patients who do not require intensive supervision and CMHCs also serve community residents who need intermittent care (US Congress, Senate Committee on Labor and Welfare, 1973). CMHCs provide comprehensive mental health services including individual assessment, diagnosis, and treatment in acute inpatient, day treatment, or outpatient settings. Unlike the UK approach, the US CMHCs were newly created agencies rather than programs reaching out from existing hospital services.

As noted in Section 7.20.2, the focus on community-based services for the elderly did not begin in the mental health system until shortly before the national initiative was terminated and responsibility was returned to the states. Perhaps for this reason, the efforts at national planning of community mental health services for the elderly that are seen in the UK are lacking in the US. However, there are model programs that can provide guidance in conceptualizing what community mental health services could offer older adults.

Knight, Rickards, Rabins, Buckwalter, and Smith (1995) reviewed a variety of mental health programs for older adults with a range of mental health problems. The programs included community mental health services in Spokane, Washington, Cedar Rapids, Iowa, and Ventura County, California, as well as a multiservice program at Long Island Jewish Hospital in New York and a psychiatric consultation service to a federal housing program for the elderly in Baltimore. The services spanned urban and rural areas and used a variety of approaches to the coordination of care. These programs have shown that it is possible to provide high-quality, community-based mental health services to the mentally ill elderly. The programs also share some common features: (i) All emphasize accurate diagnosis of older adults. (ii) All are interdisciplinary and treatment focused. (iii) All use active case-finding methods and community education approaches to bring clients in. They also collaborate actively with other agencies that serve older adults and in three cases with postal carriers, meter readers, and other "community gatekeepers" (Raschko, 1990). (iv) All of them deliver mental health services to older adults at home. Mobile geriatric outreach teams, which use home delivered services and interdisciplinary teams (see Chapter 24, this volume) have proven effective in increasing service use by older adults in both urban (Knight, 1983) and rural areas (Buckwalter, Smith, Zevenbergen, & Russell, 1991). Mosher-Ashley (1994) also has highlighted the importance of home delivered services in reaching this population.

7.20.6.2.1 What types of clients are served?

In a survey of 349 older adult CMHC clients in Miami, Pruchno et al. (1983) reported that 54% were diagnosed with a unipolar or bipolar mood disorder, 21% had dementia, and 8.9% had schizophrenia or psychoses. Speer, Williams, West, and Dupree (1991) determined that 29% of their Tampa sample was diagnosed with dysthymia, 20% had mood disorder, and 10% had maritial problems. If these local samples are representative, it would appear that CMHCs serve high proportions of depressed older adults, but may be less successful in reaching the demented and psychotic populations that were a large part of the state hospital population.

7.20.6.2.2 Were CMHCs effective in outreach to elderly?

While the CMHCs did not develop sufficient services for older adults with mental illness (Lebowitz, 1988), they did not completely overlook older adults. In fact, the use of CMHC services by older adults grew steadily through the 1970s and 1980s. The Government Accounting Office (1982) reported that 4% of all CMHC clients were over the age of 65 in 1978, whereas by 1983 the elderly comprised 6% of the users of community mental health (Fleming, Rickards, Santos, & West 1986), with lower representation in other clinics and fewer still in private practices. In the 1990s, more of the elderly have begun to use mental health services. In 1990, the Inventory of Mental Health Organizations showed that 9.72% of all outpatient mental health clinic clients were older adults; 11.87% of clients in publicly supported clinics were older adults (Stiles, 1994).

Lebowitz, Light, and Bailey (1987) gathered information from 45% of the 624 CMHCs and found that 52% of those responding to the survey provided both professional mental health services to older adults and employed a geriatric staff specialist. However, 28% of their sample had neither age-targeted services nor a staff specialist. They concluded that older adults were offered more services by those CMHCs with trained staff or specific programs. In these centers, the older adult population represented 15.8% of the entire population; among the CMHCs with no staff or services, the older adult census averaged 8%. Also, Knight (1986) reported that for county mental health programs in California, service use by older adults was predicted by the number of specialist staff and was uncorrelated with percentage of elderly in the county population.

7.20.6.2.3 What comes next?

In the mid-1980s, Fox, Swan, and Estes (1986) reported that more than 60% of CMHCs were maintaining or increasing their services for older adult populations. More recently, they reported in a follow-up study that older adults services are more likely to be dropped than added to community-based mental health programs (Estes, Linkins, & Kane, 1994). Since the control of mental health programs was shifted back to the states, they have increasingly left individual CMHCs with a reduced budget, and without any stipulation concerning how the money should be spent (Christianson & Gray, 1994). In the mid-1990s, California continued the displacement of responsibility from federal to local governments by shifting control of mental health programs from states to counties, where these services compete with the medical care system for the indigent as well as with police and fire services for funding.

It seems unlikely that comprehensive CMHCs will be a major part of mental health services for older adults in the future. As mental health services in the US move to the private sector and to managed care organizations, active casefinding and other community mental health outreach strategies are likely to be inverted with probable negative impact on the accessibility of mental health services to older adults with depression, anxiety, substance abuse, and especially with long-term mental disorders like schizophrenia.

7.20.6.3 Summary: Community-based Outpatient Services

At this level, outpatient mental health services within the UK and US diverge most markedly. The UK's history of universal coverage has led to relatively systematic programming for the elderly, including MDTs, and more recently in some areas memory clinics and family therapy clinics. In the US, the federal role in mental health services has been more research-oriented than services-oriented with the individual states playing the major role in mental health services provision (Rosen et al., 1995). The history of federal–state relationships regarding mental health in the US has been characterized by shifting responsibility back and forth between the two with neither level of government taking clear responsibility at present. As noted by Liebig (1993) with regard to health and social policies for the aged, the federal system tends to lead to wide variation in policy among states, and in some cases the absence of policy. In the mental health sector, this is perhaps most clearly the case with dementia care, which some states would include in mental health services, while others would define it as in a different system, as its own system, or as not a state responsibility (Knight & Macofsky-Urban, 1990). The US has a few model programs for community-based outpatient services for the elderly, but lacks a system or a coherent national policy.

7.20.7 PARTIAL HOSPITAL SERVICES

7.20.7.1 British Models

In the 1970s and 1980s, day hospitals developed as the central component of many local older adults mental health services. By 1990, 20 000 older people were attending such day hospitals regularly, with over 1.7 million day places available per year (Fasey, 1994). Day hospitals have served a variety of functions: preventing admission to inpatient facilities, providing relief to caregivers of people with dementia, assessment, monitoring, and treatment of people with depression, facilitating discharge from an inpatient unit back to the community, and for observing the person's behavior and mental state for a longer period than is possible in the person's own home.

There is considerable debate concerning how effective the day hospital is in fulfilling these functions, and whether it represents the most effective use of resources (Fasey, 1994; Howard, 1994; Murphy, 1994). There is relatively little in the way of evidence to inform the debate. Day hospitals have not been effective in delaying admission to long-term care (Diesfeldt, 1992; Woods & Phanjoo, 1991), but do reduce strain for many (but not all) caregivers (Gilleard, 1987). However, some caregivers find the strain of getting the person ready for day care an additional burden, or find that most of their difficulties are at night and so they are not helped by day care. A few "night hospital" programs have been developed in response to this need. The role of day hospitals in the treatment of depression has not been evaluated in the UK context.

The UK also makes the distinction between "day hospitals" and "day centers," the former are health facilities, with a team including doctors, nurses, and therapists, and the latter are primarily "social care" resources but may have input from visiting health professionals. In reality, the distinction is not always clear, and those opposed to day hospitals argue that resources spent upon them are better used to provide more health input to day centers, many of which work well in providing relief for caregivers or as a social base for older people with depression needing to expand their social network.

Although Tester (1989) argued that day hospitals generally provide respite care for those older people whose behavioral problems or level of dementia proves "too severe" to be managed in a day center setting, Warrington and Eagles (1996) reported from a specific sample that the overall level of behavioral disturbance was no greater in cognitively impaired day hospital attenders than in those attending day centers.

7.20.7.2 American Models

Partial hospital programs have expanded significantly in the US in the last 10 years and have also become a more common form of mental health service for older adults. These partial hospital programs are organized under many different models that offer a range of social and medical services (Whitelaw & Perez, 1987).

Culhane and Culhane (1993) reported that 63% of day treatment programs in the US are located in CMHCs, 17% are affiliated with general hospitals, and 12% are found in private psychiatric hospitals. As fiscal incentives promote alternatives to inpatient care, partial psychiatric services seem to be expanding rapidly, especially in the private sector. For example, Stiles (1994) reported that partial hospital services increased by 50% between 1986 and 1990. Culhane and Culhane (1993) added that older adults represent between 4.8% and 7.9% of all partial hospital patients. The American Psychiatric Association (1993) noted that partial hospitals serve 18% of those older adults who actually use professional mental health services.

Since the history of partial hospitalization is directly related to substitution for hospital-based care, it is perhaps not surprising that the population served is more similar to the state hospital population. Eskew, Sexton, Tars, and Wilcox (1983) indicated that 34% of partial hospital patients were diagnosed with dementia, 32% had an affective disorder, and 24% were schizophrenic. The patient population appears to vary by program though; Plotkin and Wells (1993) reported that 60% of their partial hospital sample were depressed, 13% had a cognitive impairment, and 9% had an adjustment disorder. The majority of these patients received treatment subsequent to an inpatient hospital stay. In a program designed and implemented at the Florida Institute for Mental Health, Roger Patterson and associates designed a behaviorally-oriented social skills training approach to day treatment which assisted chronically mentally ill older adults to return to the community from state mental hospitals. As described and evaluated in Patterson et al. (1982), the program used applied behavioral analysis, behavioral intervention, and psychotropic medication to overcome effects of chronic psychosis and chronic institutionalization. Program attenders and graduates were more successful in community placements with lower recidivism rates.

7.20.7.3 Summary

The day program model has been used quite successfully for older adults in both the UK and the US and appears to be well suited to the needs of the older adults who formerly used long-term institutional care. However, this modality of treatment has neither been extensively reported in the clinical literature nor evaluated. We would hope that it would receive more attention in future research, clinical reports, and public policy consideration.

7.20.8 RESPITE CARE

As developed in the UK, respite care generally means a short stay in hospital or in another 24-hour care setting. In the US, respite has been used to refer to community-based social services such as social day care and in-home care workers. In the UK, respite can be considered as another partial hospitalization program. As noted above, this may be one of the functions of a day care program. Often a rationale will be made as to why a particular patient "requires" respite in a hospital rather than a residential or nursing home, in terms of severity of disturbance, or of need for nursing care. The availability of resources is of course an over-riding factor in these considerations, but the need to support caregivers in this way is widely recognized.

Residential respite care involves the patient staying in a residential/nursing home/hospital setting for a given period of time, thus allowing their caregiver to have a sustained period of time off from caring. Some beds are designated as "rota beds," in that a number of patients share the resource, taking turns to come into the facility. For example, four patients might each have two weeks in hospital and six weeks at home on a rotational basis, filling one bed continuously. Some relief schemes do not run on a rota system, but allow admission over a period when the caregiver may wish to go on holiday. Relief care may also include crisis admissions, say when a caregiver is taken ill.

Nolan and Grant (1992) carried out an extensive evaluation of such a hospital rota bed scheme, concluding that respite care fulfills a deeply felt need in caregivers, but also raises issues about caregivers' attitude towards institutional care. Caregivers possess unique knowledge of their relative, and often feel that the needs of the care recipient could not possibly be met by those working in an institution who have only limited knowledge of the care recipient (Worcester & Quayhagen, 1983). It is interesting to note that although this type of respite care is generally reported as being beneficial to caregivers, they also report feeling sad and lonely when their relative is away (Pearson, 1988). Guilt and worry may also be pervasive emotions felt by a caregiver who places a relative in residential respite care (Nolan & Grant, 1992).

Evaluations of respite care have shown that it has considerable benefit for caregivers. Levin, Moriarty, and Gorbach (1994) found respite was valued highly by caregivers. When respite services were introduced, they formed an ongoing source of support. Levin et al. emphasize the need for services to be targeted to the individual, noting that one "care package" may not suit all caregivers' needs. Flexibility of service is important, especially where disease progression is an element.

Some caregivers report that the person with dementia returns from respite more confused than when he/she was admitted. This may be understood in terms of the effects of a change in environment and routine on the person with dementia, and the difficulty of staff in ascertaining quickly the person's needs. Preadmission visits to a familiar place might reduce such effects, but an alternative strategy is to provide the respite care in the person's own home to minimize the disruption for them. This service is referred to as domiciliary respite where an outside agency will dispatch trained caregivers (i.e., a "sitter" or care attendant) to the home to take over the role of the caregiver for a given amount of time—a few hours or several days. Some care workers may even spend the night at the person's home, as this is often the most difficult time. There are some indications that caregivers find these services beneficial (Turvey & Toner, 1991).

In the US, day care and in-home respite services are not typically viewed as a part of mental health service systems but rather as a part of community-based long-term care or of home health services. Curiously, these services seem more effective at meeting mental health goals (i.e., improving the caregivers' life satisfaction or reducing emotional distress) than meeting community-based services goals of reducing care costs or preventing institutional care (Weissert, Cready, & Pawelak, 1988; Knight, Lutzky, & Macofsky-Urban, 1993). However, it has long been noted that respite may not be provided in sufficient quantity to meet these other objectives, and recent research tends to support the notion that longer respite may lead to reduced institutional care (Koslowski & Montgomery, 1995)

7.20.9 CAREGIVER SUPPORT

In the UK, caregiver support groups have been a popular development from the early 1980s. They take many different forms: some are organized as "training courses"; some are akin to therapy groups, being closed and having a facilitator; many are open-ended, self-help groups. Some are organized by voluntary agencies (especially the Alzheimer's Disease Society); others are based in day centers, day hospitals, residential homes, and primary health care centers. Few evaluations have been reported of their impact, although they are positively regarded by the caregivers attending. Morris, Woods, Davies, Berry, and Morris (1992) showed no differential impact of a coping skills-based group compared with a conventional course with invited speakers on strain and depression, although knowledge and use of coping skills did increase in both groups.

Services for caregivers in mental health settings have been a prominent feature of programs for older adults in the US since 1980. In a meta-analytic summary of program evaluation literature in the US, Knight et al. (1993) found that individual psychosocial interventions with caregivers appeared to be more effective than group interventions. Fully randomized evaluations of caregiver interventions have provided mixed results regarding the effectiveness of either individual or group interventions, a finding that is more curious given the effectiveness of psychological interventions with other groups of older adults (Scogin & McElreath, 1994).

7.20.10 MENTAL HEALTH SERVICES IN THE HEALTH CARE SYSTEM

In the UK, most mental health problems (including those of older people) are managed in primary care, without recourse to specialist mental health services. It is important to note that mental health problems are common in patients admitted to geriatric units (i.e., those designated for physical health care). Burn, Davies, McKenzie, Brothwell, and Wattis (1993) reported that 43% of such admissions who could be assessed had a diagnosable psychiatric condition (30% were depressed or anxious); many others could not be assessed because of a severe cognitive impairment. Conversely, significant physical health problems are also common in those admitted to old age psychiatry units (34% in one prospective study; Perry, Milner, & Krishnan, 1995).

In the UK, the problems center on the inaction of primary care physicians rather than the lack of recognition of mental disorders in older adults by physicians, which is more common among physicians in the US (Rapp, Parisi, Walsh, & Wallace, 1988). Jenkins and Macdonald (1994) indicated that general practitioners do recognize depression in their older patients, but rather rarely respond. A randomized controlled trial of depressed patients referred from primary care to a multidisciplinary team did not show any significant benefits—but the sample was small; the authors concluded that male patients might benefit from being referred more frequently, as their outcomes were slightly better.

Blanchard, Waterreus, and Mann (1995) achieved slightly more positive results. They identified older adults with depression from a community screening survey. The older patients were randomly allocated to intervention from a primary care nurse or to "usual care" from the general practitioner. Interventions were individually designed by a MDT, and included increasing the person's social network, antidepressant medication, counseling, and the involvement of relatives. Depression scores improved in this intervention group.

General practitioners in the UK refer people with dementia to specialist services at times of crisis, or when the dementia is well advanced—hence the need for open-access services described above. Wolff, Woods, and Reid (1995) have shown that GPs mainly saw dementia as a social rather than a health problem, and felt that early referral was unhelpful. They felt that they had little to offer patients with dementia, and this sense of helplessness may contribute to the failure to refer. Primary care teams are now encouraged to carry out an annual screening of individuals over the age of 75. This normally includes a rudimentary assessment of mental state. Consequently, the awareness of patients with dementia in the primary care context could grow.

In the US, there has been an increasing recognition that the health care system in general, and physicians' offices in particular, are a *de facto* part of the system of mental health care in the community. Analyses of service utilization data by George, Blazer, Winfield-Laird, Leaf, and Fischbach (1988) call attention to the fact that adults of all ages with a mental health problem are more likely to go to a health care provider than to a mental health professional. This tendency to seek mental health care from primary care physicians rather than from mental health professionals also appears to increase with age after the age of 55.

What happens during these visits is less clear. Physicians have been shown to be poor at detecting depression in medical impatients (Rapp et al., 1988) and outpatient service provision does not appear to be any better. Katz (1996) reported that primary care doctors often misdiagnose or overlook depression among older adults—one survey revealed that 26.4% of primary care physicians never evaluate the emotional status of individuals over the age of 75 (Mann, 1995). Further, primary care physicians tend to treat mental health problems only with psychotropic medications (Burns & Taube, 1990). These physicians are not likely to conduct clinical histories, involve family members with treatment, or to use psychosocial interventions.

Haley, Salzberg, and Barrett (1993) reported that geriatric specialists in medicine tend to be more open to psychological interventions and to working with psychologists as part of the care team than primary care physicians without geriatric training. Haley (1996) has also argued for the importance of staffing medical clinics with psychologists as part of the outreach effort to assure that older adults in need receive adequate services.

In short, it appears that on both sides of the Atlantic, mental health services for older adults are moving into the medical care system. While the move is conceptually unassailable and has the potential to improve access to mental health services and the coordination of mental health and medical services, short-term results suggest that the result may be decreased access to mental health services due to ineffective screening and intervention by primary care physicians. The multiple systems perspective would suggest that the medical system will, of course, recognize and treat medical disorders rather than mental health disorders and so the elimination of the separate mental health system may be undesirable.

7.20.11 DISCUSSION

7.20.11.1 Cross-national Systems Comparisons

The contrasting histories of mental health service systems in the UK and US are reflected in much of our previous discussion. While both systems have seen the demise of the large institutions, in the UK a long-term tradition of universal health care coverage and parity of coverage between mental health and health services created an environment in which old age psychiatry has developed as a new and influential speciality in psychiatry. New-style, community mental health services have been established with the resources released by hospital closure. However, as Murphy (1994) points out, not all the services that the asylums offered have been replaced. Extensive social support, health care, and social care resources have not been developed extensively. In the UK, institutional care still absorbs most of the available resources, despite preferences of families and older people and the stated aims of services.

In the US, community-based programs for older adults have never been well-funded and continue to face major threats to funding. Historically, federal policy in the US has placed restrictions on mental health services as supported by Medicare and Medicaid health insurance programs. These restrictions are beginning to be eliminated in the 1990s, but it is too early to assess the impact of increasing Medicare reimbursements to more providers or of recent moves toward parity in mental health insurance reimbursement. In summary, both nations have been more successful in closing down the institutions than in creating substitute systems in the community.

Research in both nations has focused on dementia and depression (rather than anxiety, alcohol abuse, or older schizophrenics) and on outpatient services rather than on inpatient or partial hospital services. These tendencies need correction to provide an empirical basis for comprehensive services in clinical geropsychology.

7.20.11.2 Dementia Services

The nature of services for older adults with dementia also differs. In the UK there is considerable focus on services to demented people themselves within the mental health sector with active concern for improving the well-being of the person with dementia. Kitwood (1996) provides a timely reminder of the "personhood" of the patient with dementia—psychological approaches to dementia must entail ensuring that the full human needs and potential of older people with severe cognitive impairments are recognized and nurtured. He contrasts his approach with the "neurological determinism" of the traditional model of working with the demented. The US, perhaps caught up in the "neurological determinism" viewpoint, has tended to conceptualize services for dementing elderly as services for the family caregiver and often places dementia services outside of the mental health sector: in social services, aging services, and so forth.

7.20.11.3 Mental Health and Primary Care

In the UK, mental health services for older people are likely to be provided in primary healthcare settings (see Mann, 1995) where most older people with mental health problems are actually found. A new relationship with the independent sector providing consultation outside the traditional NHS and Social Services settings needs to be established. This is a remarkably difficult change for clinicians brought up to feel that the NHS should provide care "from the cradle to the grave," at no cost at the point of service delivery.

In the US, the same change is likely to occur, driven in large part by the increasing organization of both health and mental health care into various types of managed care networks of providers. In the US, where the private sector is the traditional provider of health care and of much outpatient mental health care, resistance to these arrangements has more to do with the traditional independence of mental health providers and the differing organizational cultures of medical and mental health care. The latter reason has been offered as an explanation for the tendency to rely on separate managed care provider organizations for mental health services (Wholey, Christianson, & Peterson, 1996).

Indeed, as both nations move toward versions of managed care, primary care physicians will assume increased control over the provision of health and mental health services. For different reasons, this change may not bode well for access to required services since primary care physicians have not shown a great willingness to refer older adults for required mental health services (the UK) or even to recognize the need for such services (the US). In both cases, the problems may stem from the distinct world views of physical medicine and the mental health disciplines, a gap which must be bridged in order to effectively serve older adults. Creating the required levels of communication and collaboration will require orienting the two worlds to one another's languages, professional practices, and folkways (see Chapter 24, this volume; Qualls & Czirr, 1988).

However, as noted in the beginning of this chapter, older adults have a variety of medical, social service, and mental health needs which have traditionally been served by multiple systems of care, each with its own expertise, organizational structure, and economically driven imperatives. Mental health policy for the last few decades has tended to assume that people in general and older adults in particular would be better served by a single, formally organized system. Yet, participant observation would suggest that formal attempts to coordinate services have a tendency to serve the needs of the organization rather than those of the client; that is, groups of providers come together to discuss how to prevent clients from overusing services or to impose organizationally defined models of "appropriate" service use on the client. Myrtle and Wilber (1994) argued that a modern organizational theory, "loosely coupled systems," may better describe the functioning of services for the aged and also be a better model for assuring that the client gets the best services. Interlocking multiple systems can assure that specialized services are available for the client's multiple needs; restricted access systems (e.g., "single point of entry" and so forth) are likely to create barriers to some needs being met.

A salient example is the attempts in both the UK and the US to funnel older adults with mental health problems through primary care medicine, a gatekeeper strategy that seems likely (perhaps unintentionally) to deny care rather than assure it. An empirical test of an organized system of mental health care for children in the US (the Fort Bragg Demonstration) showed that the organized system provided better continuity of care but that clinical outcomes were no better and the cost was higher than in the business as usual fee-for-service system (Bickman, 1996).

Older adults often need a wide range of services from several different service systems and their needs may be met more effectively by an informed consumer who negotiates with the loosely coupled systems and interacts with those professionals who collaborate with other systems ("interpersonal coordination," Myrtle & Wilber, 1994). Their needs are less likely to be met within artificially constrained "megasystems" whose organizations make the individual systems less adaptable to specific, changing problems. Myrtle and Wilber (1994) argued that, over time, the informed consumer and gerospecialists would be expected to evolve their own norms for coordination of care and perhaps create a new aging-centered network of services in which current boundaries (e.g., between health and mental health or between mental health and social services) would have withered away.

7.20.11.4 Roles for Clinical Psychology in Community Care

There are many areas in community care where a key role could be assumed by a clinical psychologist. (i) In assessment, it is clear that individualized approaches are required to provide care in the community—in memory clinic contexts and elsewhere, neuropsychological assessment and professional consultation with other professionals is valued. The identification of neuropsychological problems underlying behavioral difficulties is important as is greater attention to differential assessment of emotional distress (anxiety versus depression) and personality disorders in older clients. (ii) Depression and anxiety are responsive to psychological treatment approaches (see Scogin & McElreath, 1994; Woods & Roth, 1996), and their adequate treatment would reduce a great deal of suffering. This treatment could be provided across a number of community-based systems. (iii) In support for family caregivers, there is evidence that psychological factors mediate strain and depression in family caregivers, and the development of more effective programs with psychological underpinning is desired (see Knight et al., 1993; Woods & Roth, 1996). (iv) In prevention and systems-level analysis and intervention, there is a strategic role in evaluating and developing more effective community services, and a need exists for a systemic approach to thinking, practice, and evaluation. For example, outcomes for caregivers and for their relatives with dementia cannot be viewed separately and in isolation. Also, the realities of elder abuse need to be considered alongside caregiver strain. The risk factors for institutionalization need to be understood more fully, along with better insight as to when entry to a nursing home is a good outcome for all concerned.

7.20.11.4.1 Development of clinical geropsychology

Clinical psychology with older people has had contrasting histories in the two countries. In the UK, in the 1960s and 1970s contact of clinical psychologists with older people concerned assessment, usually to attempt to answer the depression vs. dementia question. Very few psychologists specialized in aging. This changed during the 1970s when a small group developed a special interest in the field and explored a much broader range of roles, including treatment approaches to depression and dementia. By 1980, a formal interest group was formed and membership has continued to grow dramatically. The training of all clinical psychologists in the UK now requires experience in working with older adults, which includes working with people with depression and dementia and with family caregivers.

In the US, specialization in aging within clinical psychology developed later and more slowly. The first meeting on training psychologists to work with the elderly was held in 1981 (Santos & VandenBos, 1982). A follow-up conference in 1992 provided mixed impressions of the growth of the specialty during the 1980s (Knight, Santos, Teri, & Lawton, 1995); university-based training showed little expansion although internship training, especially in the Veterans Affairs hospital system, had expanded (Cooley, 1995). The national organization for clinical geropsychology in the US was formed in 1992 (Knight, Santos et al., 1995). Training for psychologists in aging is not widespread in the US and not a requirement for all psychologists as in the UK. The training models in the US emphasize university teaching and research, Veterans Affairs or university medical center employment, or independent practice as eventual employment opportunities in clinical psychology. Training and working within community-based mental health programs has been relatively ignored, except for the use of community practica in training geropsychologists (Qualls, Duffy, & Crose, 1995). Few psychologists with expertise in clinical geropsychology are found in community settings (Knight, Rickards et al., 1995; Qualls et al., 1995). Psychologists in the US are also facing increased competition from master's level providers not identified with psychology (e.g., clinical social work, marriage and family therapists). These other mental health professionals are employed as a less expensive provider of psychological services, especially under managed care approaches.

Training programs need to rethink their goals to train psychologists for the jobs of the twenty-first century. Clinical geropsychology tends to be progressive in its emphasis on the interface between medicine and mental health, between social services and mental health, and placing psychologists into nontraditional settings. The future of clinical geropsychology depends upon developments in public policy and in the management of health care services over the next several decades. Certainly, it would be helpful for clinical geropsychologists to study the successes and failures of colleagues in other countries.

7.20.12 SUMMARY

In both nations, clinical geropsychology can offer a great deal to the delivery of services to older adults. Clinical geropsychology focuses on the clinical psychology of medical illnesses, on services to demented older adults, and involves psychologists in services and research across a wide variety of hospital, partial hospital, clinic, and community settings. Training and practice in community-based clinical geropsychology is inherently multidisciplinary in focus. Clinical geropsychologists, like geriatricians and other specialists in aging services, are likely to be well-positioned on the mental health side for the kind of collaboration required to make the loosely coupled systems of services work for older adults.

7.21.1 INTRODUCTION

Should a separate approach be taken to mental health for the aged in nursing homes? Could we not comprehend treatment of the aged in nursing homes as we comprehend the aged in the community? The answer is no. Furthermore, elaboration of this issue has been neglected, especially in light of the growing elderly population residing in nursing homes. This causes damage and reduces the quality of life for the elderly. While there certainly are similarities in the mental health approach to nursing home and community residents, there also are clear differences and unique demands of psychological treatment in nursing homes, based on specific knowledge of conceptualizations and clinical methodology. The absence of such knowledge hinders the function of the geropsychologist. The question whether elderly should age in organized and institutional frameworks of one kind or another has concerned modern society for many decades. But while debates continue as to the best, or necessary environment for the elderly to age, the fact is that in the postwar era organizational and institutional frameworks for the elderly have grown steadily. This growth parallels increased longevity and what is termed the "demographic revolution," that is, the colossal change in the population age structure, patterns of habitation, and the implications of these in all domains of life. Demographic projections suggest that the number of nursing home residents will triple in the 1990s (US Senate, 1987) since at least one person out of five will be institutionalized (Palmore, 1976). Keeping in mind that the needs of the elderly for mental health are extremely high, that psychiatric and medical institutionalization is unsatisfactory, and that the question of the appropriate residency in the later years is unsolved, there is a real danger that nursing homes will turn into centers inhabited by the most maladjusted elderly.

At the outset the reader was asked to bear in mind that many elderly do not suffer but enjoy their residency in nursing homes and experience well-being, development, and growth. Unfortunately, however, the problem of mental health in nursing homes is colossal. In this chapter, after defining the approach to mental health in the elderly, the issues of mental health as they appear in homes for the aged are addressed. The threats to adjustment of elderly people before, after, and during their relocation to homes for the aged are then delineated. To this end, the different nursing homes are noted as well as their inhabitants and then the utility of the nursing home is discussed, as well as the effects of institutionalization. This leads to an examination of the transitional process, the implication and effects of relocation, as well as the problems to overcome and the tasks to be achieved, in order for satisfactory adjustment to the new environment and for the preservation of mental health. While the initial focus is on the psychosocial process of adjustment, the prevailing psychopathology in these homes is discussed and then a psychological community-oriented clinical model is proposed, before a discussion of its organization and implementation as it applies to methods of treatment, including consultation, psychotherapy, and education, to staff and residents in nursing homes. The chapter ends with a future perspective on clinical geropsychology in nursing homes.

7.21.2 MENTAL HEALTH IN OLD AGE

7.21.2.1 Definition and Approach

The focus here is on the elderly person's ability to cope with personal aging processes in a specific, changing environment. Mental health is approached in the same way as those perceiving it beyond the absence of pathology. The modes of intervention and treatment are in line with such a broad perspective. The World Health Organization (1964) defines health as "a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity" (p. 1). While many scholars are concerned with psychopathological aspects of mental health, the "positive mental health" approach (Jahoda, 1958) attempts to better understand the role of adaptive processes. Birren and Renner (1980) relate to four components in the concept of mental health: (i) the presence or absence of mental disease, (ii) the presence or absence of deficits or limitations in behavior, (iii) the satisfaction or contentment that is derived from one's life as it is being lived or has been lived, and (iv) some approximation of an ideal person. While the relevancy of (iii) and (iv) to the elderly could be understood in light of history, socialization processes, and life-review of the elderly, (i) raises problems since many elderly suffer from "social pathology," for example, loneliness (Pfeiffer, 1977) even in adjusted living, and (ii) is certainly complex since old age goes along with deficits and limitations in behavior. While mental health for the elderly may include many of the components applied to the young, such as adequate life satisfaction, self-acceptance, mastery of the self and environment, the ability to work, love, and play, the manner in which these criteria can be met changes in old age (Gatz, 1989).

While older adults experience the complete range of psychopathology seen in younger age groups (Knight, Santos, Teri, & Lawton, 1995), three points should be emphasized (Schaie & Willis, 1996). First, older people perform differently than younger on virtually all psychodiagnostic instruments, often resulting in inadequate assessment of their pathology. Second, in old age there is a high rate of physical or psychosocial loss which may constitute risk factors in mental illness. The third point concerns the major individual variability in old age. Some elderly may increase their psychological vulnerability through repeated inability to cope successfully with life stressors, while others may increase their sense of mastery as they improve resilience and become more resistant to mental illness. One should therefore be aware of the fact that applying various standards of mental health to the elderly in general, and to those residing in nursing homes in particular, is complex and requires clarification on the part of the clinical gerontologist.

A development-growth and not a depletion model is adopted to the elderly, in line with Gutmann (1994) who states that the second half of life should be viewed "neither catastrophically nor sentimentally; it is neither an exclusive tale of losses nor a golden age. Like any other sector in the life cycle, it has its own distinctive depletion, it has its own gains, and makes its own special contribution to individual development, social cohesion, and species continuity" (p. xviii). However, while adhering to this approach there is an awareness that due to, between others, lessened income, physical losses, poor health, enforced isolation, environmental relocation, retirement, interpersonal losses, widowhood, or the effects of drugs, many older persons cannot function according to the various standards of mental health. Elderly, especially in nursing homes, cannot always be autonomous and master their environments. They may lack the financial or personal and interpersonal resources to make decisions about their lives and, for certain individuals in specific situations, depression, hostility, apathy, or anxiety may be legitimate or even helpful (Gurland, 1973). Internal and environmental stress in the elderly may be more apt to produce mental disorder in the face of reduced physical and psychological reserves (Gatz, 1998). Therefore, when assessing the mental health of the elderly, it is more crucial to take into account the complete organism total life ecology, relocation being is a point in case. Exposition and explication of one's theory is crucial. Adherence to an adult developmental life-span approach is advocated (Baltes & Baltes, 1990), embedded in positive mental health as noted above and urge caution in defining and juxtaposing the different manifestation of "mental health" vs. "mental illness."

7.21.2.2 Mental Health In Nursing Homes

The problems in later life are singularly appropriate for psychological treatment. They include organic and cognitive loss, coping with stress, identity roles, interpersonal and family behavior, neurosis, psychosis and, indeed, every category to be found in any version of the *DSM* (Bienefeld, 1990). Although the magnitude and severity of the mental health problems in the elderly and their need for care are obvious, the extent of the treatment provided is severely limited and most needs are not met. The aged receive disproportionately less mental health services. It is estimated that only about 3% of all clinical services provided by psychologists go to the older adult population (Gatz, Popkin, Pino, & VandenBos, 1985). Given the higher rates of mental illness in homes for the aged, mental health care is proportionately even less then in the general population. Longevity may have increased, but not the quality of living.

Although many elderly persons enter long-term care institutions to improve their quality of life, unfortunately, the result is, at times, the opposite, with detrimental effects, often due to the inadequate quality of care (Kane & Kane, 1982). While mental disorders and symptoms are estimated between 15 and 25% (Schaie & Willis, 1996) for the population over age 65 years, in medical and institutional settings, such as nursing homes, the figure is dramatically higher, generally estimated to be in the range 60–90% (Cohen, 1991; Gatz & Smyer, 1992). A major criteria for mental health is a person's ability to cope with their environment. For many who are unable to live independently in the community, this criteria has to be met in adjusting to a nursing home. The absence of a caregiver or the lack of social support networks distinguishes most nursing home residents from equally impaired elders dwelling in the community. Twenty-five percent of nursing home placements are precipitated by the illness or death of the caregiver (Colerick & George, 1986). In the early 1980s, a national nursing home survey (Eisdorfer & Cohen, 1982) found that 30% of nursing home residents had "diagnosable" psychiatric disorders and that 61% had one or more mental impairments. While more older adults have dropped out of, or never entered, the mental health system, other organizational settings, notably nursing homes, have become the service destination for the mentally impaired elderly (Johnson &

Grant, 1985), especially since the Deinstitutionalization Act (Goplerud, 1979). Donahue (1978) estimated that 40% of the patients discharged from public mental hospitals eventually found their way into nursing homes. Despite the fact that a majority of nursing home residents are in need of mental health services (Newman, Griffin, Black, & Page, 1989), these settings are designed and staffed primarily for physical, rather than mental, health care (Smyer, 1989). In most nursing homes the staff is also untrained and too overburdened to deal with emotional problems, some of which are exacerbated or developed as a result of living in the home.

Psychotherapeutic mental health programs and provisions are rare. Psychiatric visits or consultations are the exception to the rule (Johnson & Grant, 1985). It has been noted that "the tragic irony about nursing homes is that they represent a major setting for the mentally ill, with grossly inadequate mental health attention" (Cohen, 1980, p. 983). There is a strong urgent need for interventions by mental health professionals such as psychiatrists, psychologists,or trained mental health social workers in order to handle the severe problems of mental health in homes for the aged.

7.21.3 NURSING HOMES: DIFFERENT SETTINGS OF LIVING AND CARE FOR DIFFERENT POPULATIONS

Although the generic term "nursing homes" has been adopted, the reader must realize the variability of these institutions. These habitats range from "sheltered homes" to "homes for the aged" to "convalescent homes." They differ in segregation (isolation from the outside world), policies, and control (the degree of autonomy permitted to patients). They range from "open" to "closed" institutions or floors, providing partial to total care, from secluded rural to urban community settings. They vary widely in quality, regulations, in the focus on instrumental and/or also social and affective needs, and offer various degrees of help in daily living. Some offer basic nursing and custodial care while others provide a variety of services to restore, or maintain, the residents' ability to function. Support in various homes may be related to the amenities and regulations of the facility and to the availability of more than minimal staff and care resources (Timko & Moos, 1990). Smaller facilities may, in certain instances, be more constructive since they resemble a home environment, better meet the resident's needs, and minimize the impact of institutionalization. As the size of the institution increases, the quality of communication, satisfaction, and active involvement of residents may decline (Schaie & Willis, 1996). It should be emphasized that the different structures and kinds of nursing homes bear different implications for their residents' behavior in terms of social life, humanistic or dehumanizing atmosphere, adequate health care, independence, control, well-being, and mental health.

Just as there are major difference between the various nursing homes, so do the residents differ in personality, coping abilities, mental health and cultural background. However, some generalities may be drawn. Generally, in contrast to the elderly dwelling in the community, most nursing home residents have the following in common: (i) their age is higher: 75% over 75 years of age and 35% of these are 85 or above (forecasts for the year 2003 suggest that 87% of nursing home residents would be over 75; National Center for Health Statistics, 1983); (ii) the majority are widowed; (iii) more have no surviving immediate family member living nearby; (iv) they are more functionally disabled; and (v) many more suffer from physical or mental problems as well as from chronic physical conditions involving pain, threat of hospitalization, and gradually increasing impairments.

7.21.3.1 Mental Health and the Role of Nursing Home

The function and utility of the nursing home in society is influenced by social forces, policy, economics, family structure, commitment, and social values. However, the climate and physical environment in which people live and work is related to life expectancy, stress, and various medical, physical, and mental disorders (Wantz & Gay, 1981). Nursing homes, therefore, determine to a great extent the well-being and mental health of their residents (Lawton, 1985).

For the elderly person with some deficit in self-care ability, the nursing home answers the major need for tending and care. It provides security, protection, and safety and assists in the activities of daily living. Usually nursing homes also attempt to satisfy the additional basic needs for shelter and human comfort. The family expects the nursing home to become a surrogate fulfilling the dual aspects inherent in the notion of care: providing concern, support and morale, as well as performing the direct work of tending. As illness, frailty, or loss in resources and support systems are often the background leading to nursing home admission (Hirschfeld & Fleishman, 1990), they highlight the fact that those admitted are vulnerable and in need of psychological support, in addition to tending. One task of the psychologist in nursing homes is to ensure that residents also receive mental support and care along with physical care.

Various studies indicated psychological and social improvements following the move to public housing facilities or retirement community centers (Lawton & Cohen, 1974), especially in homes which were designed specifically for the elderly and the residents themselves choose the home. However, disagreement exists with respect to effects of rehousing on health, and many studies found negative effects of relocation (e.g., Lieberman & Tobin, 1983). Butler (1975) claimed that most elderly people view the move to a nursing home with fear and hostility and believe that the move to an institution is a prelude to death. Farrari (1963) compared two groups moving from home to an institution, one voluntarily and the other with no option, and found that 10 weeks later mortality among the latter was to be extremely high. Lawton (1980) suggests that the differences in findings may be due to the variability in the quality of housing, sampling, economic status of inhabitants, and personality variables as well as to research design differences. Determining, in varying degrees, are also the detrimental effects of institutionalization.

7.21.3.2 The Effects of Institutionalization

Nursing homes are institutions and as such their inhabitants are subject to the effects of institutionalization. The very nature of an institution contradicts the nature of a "home," which implies intimacy, autonomy, privacy, and control. As Tobin and Lieberman (1976) state "it is difficult to avoid the implication that even the finest institutions cause the deleterious sequale commonly refered to as *institutional effects*" (p. 5). Basic factors leading to institutional effects include: physical and human ecology, territory and space constructions and limitations, the structuring of time, sharing of space and interaction with neighbors, regimes, inspections, routines, the burden of authority, use and abuse of dependency, ritualizations, stigmation, the impact of crowding, lack of privacy, group pressure, and engulfment (Goffman, 1961). Negative effects upon inmates of institutions include: changes in self-perception, feelings of inferiority, dependency, alienation, stress, depression, somatic and mental illness.

Such general factors have specific manifestations, impacts, and detrimental effects in nursing homes. The negative stereotyping of society incorporated by nursing home staff (Wright, 1988) may result in a negative atmosphere in the home and a lower self-concept of its residents. Insecurity and insufficient privacy (Firestone, Lichman, & Evans, 1980) may cause a sense of intrusion and fluidity of personal boundaries. Limitations in providing care may result in loss of self-esteem, estrangement, isolation, and deindividuation (Tobin & Lieberman, 1976). Low quality of care (Johnson & Grant, 1985; Kane & Kane, 1982), lack of sufficient personal attention, and respect may all induce depressive moods. Constricting freedom and control may be detrimental. Rodin and Langer (1977) have demonstrated how reducing restriction of choice and control in a home for the aged resulted in increased alertness, activity, and general well-being, while increasing restrictions have the opposite effect. They conclude that "some of the negative consequences of aging may be retarded, reversed, or possibly prevented by returning to the aged the right to make decisions and a feeling of competence" (pp. 897–902). Perlmuter and Monty (1979) suggest that the major problem for residents is the inability to exercise choice, control, and personal responsibility which then has a harmful effect on well-being and adaptation. Residents should be given greater control of their daily lives as well as participate in decisions affecting various aspects of the home's programs and policy (Moos & Lemke, 1985). Studies in social ecology of nursing homes show that reinforcing independence not only reduces dependence but also reduces the incidence of disease and death (Baltes, 1982).

Assembled in a common environment, the newcomer to the nursing home cannot escape the dreaded identification with their surroundings which include being sick, yearning for care, and feeling closer to death. In order to adapt, they have to participate with others in the cannons of the institution, but in doing so they may lose uniqueness, and become discontent, bitter, and hostile. The institutional structure and atmosphere may restrict or promote interpersonal and social contact (Hansson & Carpenter, 1994). It may decrease family visits leading to loss of contact with family members and friends. As family members recede into the background, the position of the institution as the last and "only" home for the elderly person is reinforced. The environment then signifies vulnerability, mutilation, and death, but at the same time protection and survival. Given all the above it should come as no surprise that individuals in nursing homes are significantly lower in psychological well-being than individuals with similar levels of physical and social function living in the community.

The impact of institutional processes, including staff burnout, may be so great as to undo and render useless the effects of professional therapeutic interventions (Lomranz, 1991).To counteract this impact, nursing homes should be viewed as communities whose subsystems mutually interact with the broader surrounding community and its social policy dimensions. At the same time, investment in nursing home staff should be aimed at active preventive programs to counteract institutionalization.

The chapter will now discuss the specific issues of the processes and mental health implications of moving to a nursing home and the factors involved in adjustment and adaptation.

7.21.4 MENTAL HEALTH IN LIGHT OF THE TRANSITION AND ADAPTATION TO A NURSING HOME: COGENT ISSUES

The transition to a nursing home involves significant change, including separation, loss, and readjustment. For many it means "closing" a 60+ year chapter of their lives. The new location encompasses a novel territory, neighborhood, social group, entire community, and access to the outside, larger world. The location chosen, its atmosphere and culture may be crucial. For most people a house is a meaningful life-space: "home is where the heart is." Home signifies stability, roots, a feeling of belonging, security, identity, intimacy, personal space, and generativity. Permanently relinquishing one's home can be a painful step. This surrender is especially hard for the elderly person who experiences many additional changes and may cling to the familiar for security and permanency. Thus, the need to adjust to a new framework involves the ability to separate emotionally from a previously meaningful stable world, that is, from habits and lifestyle held throughout many years, from defined identities, and from a familiar society and environment. Successful relocation, therefore, is a complex twofold process that requires reconciliation with loss as well as adaptation to a novel environment. The rationale to move to a nursing home, adjusting and maintaining well-being along time, all depend on a wide range of personal, interpersonal, and environmental resources. These include a complex range of factors, such as, individual characteristics and ego resources, past history, family structure, quality of relationships, economic status, social background, environment, and culture. Once in the nursing home, a variety of adaptational task are expected. Given the variability in nursing homes and in coping patterns of the individuals, it is almost impossible to predict adjustment patterns. Nevertheless, some basic factors are highlighted which are deemed critical to the adjustment process.

7.21.4.1 The Decision-making Process and its Impact

The decision to leave home and move to a nursing home is an emotionally-loaded process involving multiple aspects, phases, and actors (Groger, 1994). This major life decision often involves anxiety, stress, ambivalence, fears, doubts, hopes, and risk taking, feelings which may be unavoidable considering the life changes involved and the necessary uncertainty about the new habitat and the future. The family often plays a major role prior to admission and, thereafter, in the readjustment of the elderly. Overt and covert individual and family conflicts may often emerge. Family members frequently share the elderly person's ambivalence (Bar-Tur, 1993; Halpert, 1991). Institutionalization of an elderly parent may also create family crisis. Moreover, data suggests that above 50% of those entering homes for the aged do so without having taken a meaningful part in the decision-making process (Reinardy, 1992).

The decision-making process affects the person's adjustment to the nursing home. Elderly who exercised more control over the decision adjust better than those who have less control over the move. Often an elderly person may feel "dumped" by their family and consequently become alienated and depressed. Family structure has major impact. Having, for instance, one daughter or sibling reduces an older person's chances of admission by about one-fourth (Freedman, 1996). Sometimes family members act out conflicts in their relationships with the nursing home staff, further complicating the adjustment process. Children may seek professional help in the process of placing their parent in a nursing home. Guilt, anger, regret, and resentment are almost ubiquitous. Planning and implementing the decision with the family in a context of safety, nonthreatening, and open communication can minimize distortion and promote healing of the family (Bienenfeld, 1990). The psychological loaded milieu described here obviously indicates the possibilities for clinical geropsychologist to assist in conflict resolution and stress reduction for all those involved in this transition and relocation. At stake is not merely "adjustment" to the nursing home, but solving existential dilemmas to improve the quality of life.

Over one-half of the persons admitted to a nursing home are discharged within three months. This figure includes those who die as well those transferred to hospitals or to the community. Most of the hospitalized, as well as those discharged to the community, eventually return to the nursing home (Lewis, Cretin, & Kane, 1985). Cooperation between hospitals, the community, and nursing homes is crucial, especially when dealing with the chronically sick elderly.

7.21.4.2 Preadmission Screening

Elderly adults admitted to a nursing home usually present a combination of mental and physical health problems. Potential patterns of interaction between physical and mental health conditions among nursing home residents may be expressed in the four categories of (i) "classical" psychosomatic disorders; (ii) somatizing responses (e.g., conversion syndrome); (iii) physical illness causing psychiatric symptoms; and (iv) psychological responses to illness. Family and social issues are often embedded in all these. The preadmission screening procedure is therefore very important for certifying the type of care, mentally and physically, the new resident requires (Symer & Garfein, 1988). It may add clarification to the decision-making process as to the kind of home to seek and may lay the basis for the kinds of interventions needed to assist the individual's adaptation in the nursing home. It is recommended (Newman et al.,1989) that psychologists become more involved in the substance and process of preadmission screening, assessment being one of the applied psychologist's strengths. Depending on the results of the prescreening, the clinical psychologist may further refer the candidate to a medical, family, or consulting psychologist as well as to social workers.

7.21.4.3 Adaptational Tasks in Nursing Homes

The transition to a nursing home requires various adjustments. Some of the major tasks, in specific areas of daily living, that must be accomplished to promote an appropriate quality of life in the nursing home, are outlined in what follows.

7.21.4.3.1 Limited living space and seperation from personal effects

Exchanging a macro- for a microenvironment implies radical reorientation of spacial experience. Personal and interpersonal space has to be modified. Transition to diminished space, sometimes sharing one room with someone else, requires residents to limit drastically their living space and separate from many objects they have accumulated throughout many years. In such objects, a person's history, identity, and lifestyle are encapsulated. Separation from such meaningful objects, in addition to other losses experienced in old age, may create a painful sense of discontinuity. Relocation sometimes involves rapid renunciation, resignation, and separation, whereas mourning over the losses may be prolonged. For example, about one year after admission, Mrs. B. realized at her birthday party that she didn't have a single flower vase. She burst into tears at the memory of all the beautiful things she had been forced to leave behind, expressing a sense of deprivation. Mr. Z., a widower without relatives, negotiated for two years with a nursing home for them to accept him with his 200 books; he passed away, bitterly, in midst of negotiations. Neither had any contact with a mental health professional. Stripped of personal belongings and yearning for them may cause depressive mood. Attachment to familiar objects lends a sense of security and may serve as an adjustment mechanism. While the importance of transitional objects in young children (Winnicott, 1953) is recognized, they should be considered significant throughout the life-span. Just as the child therapist may utilize transitional objects to reinforce growth and development, the geropsychologist may do the same, but usually on the basis of the absence of such objects.

7.21.4.3.2 A novel geographic ecology

Adjustment to ecology includes the physical environment, the world of plants and animals, the human inhabitants, and the larger geographical surroundings. It also signifies the importance of environmental planning for older people (Moos & Lemke, 1985) and the behavioral and affective outcomes in the person-environment fit. Geographic experiences, defined as "the individual's involvement within the spaces and places of his life" (Rowles, 1979, p. 81), represent meaningful dynamics in the individual. Organization of a new living space is difficult. Residents must familiarize themselves with a whole new world. Mrs. B., a 90-year-old lady, said sadly "I lived in the same four-room apartment for 60 years, and everything had its place. Here, in one room, I have hardly anything and I still can't find nothing." The required adjustment not only concerns one's room, but also the facilities in the building and the surrounding area. Uncertainty as to what is usually posited firmly in our minds (e.g., rooms, buildings, streets, or bus schedules) may cause disorientation, especially for those who are confused, leading to anxieties and nightmares. Coping and adjusting to the ecological aspects consumes physical as well as mental energy but is crucial for enabling the residents to "feeling in place" and enhances belongingness.

7.21.4.3.3 *Structured and leisure time*

New residents face a transition from controlling and structuring their time, in the past, to a milieu in which almost all the time is structured for them and they also may be discontent about the way time is filled. Life in many nursing homes goes by a strict time schedule. There are specific hours for such things as eating, social activities, and receiving medication. Moreover, often these time-bound activities become the most significant events, the markers and content of existence and, as such, being after all very simple routines, may render the totality of life for the resident as boring and meaningless.

Transition to a nursing home frees time and energy that in the past were devoted to activities of independent daily living. Potentially individuals may enjoy, as many do, and use their time for a variety of creative and educational activities. However, although being released from burden and given freedom for pleasure and personal enrichment, many residents may find it difficult to shift from fulfilling duties to enjoying leisure time. Such an inability to shift relates to the difficulty in giving up roles, values, identities, and lifestyles, all molded during one's life-span. Neulinger (1981) postulated that the ability to enjoy leisure time depends on a certain mental state that includes a feeling of freedom together with basic motivation to experience and enjoy. Physically or emotionally frail residents may find it hard to learn new outlets for satisfaction and as a result experience low morale. The passage of time may also be experienced as monotonous, slow, and dispersonalized, features associated with the depressed elderly.

Further implications of temporality refer to the personal experience of time (Lomranz, Shmotkin, & Vardi, 1991) such as time perspective or the meaning of future time. Such aspects retain specific significance in the existence of nursing home residents and they present furtile ground for the work of the clinical geropsychologist.

7.21.4.3.4 *Food and communal dining*

Gutmann (1994) found, cross-culturally, food and oral preoccupation to be a major avenue of joy and pleasure and of highest significance for elderly people. Many nursing homes operate on the basis of communal dining and the issue of food becomes a major adaptational task for the resident. Coupled with changes in sense of taste, as well as the loss of familiar "home food," losing the role, especially for women, of "cook," and communal dining, can all be extremely frustrating and may become a major source of friction between residents as well as with staff. For an elderly resident, oral intake sometimes constitutes the only source of gratification and a main channel of communicating, interacting, and coping with the caretakers at the home and the world at large. Food, its quality and associated eating rituals, the conflicts as well as memories around it, all indicate personal and interpersonal significance. The psychological features associated with food: satisfying, receiving, giving, and caring, the ability to manipulate food as a means to interpersonal contact, are all severely restricted in communal dining and bear psychodynamic implications regarding mental health of residents, that the geropsychologist should be aware of.

7.21.4.3.5 *Interpersonal and social adjustment*

Adjustments in the interpersonal sphere and the social environment are perhaps the most crucial for the resident. The social circle, including residents as well as staff, is large, unknown, and unstable. Yet, new relationships have to be established. Many nursing homes are planned to have more than one resident per room. For some, the hardest tasks in adjusting to a nursing home are sharing personal space with a roommate, and forming a long-term intimate partnership. This requires a great deal of flexibility, compromise, and willingness to forego independence and freedom of choice regarding daily issues (e.g., when to turn out lights, cleaning and tidying, use of toilet, etc.) which take on increasing significance since they represent basic needs such as territory, belonging, or boundary intrusions, and become the ground for feelings of rejection, insult, or elicit aggressive behaviors.

Stripped of their previous acquaintances and social markers, the resident may feel insignificant and worthless. Loss of identity, together with the need to integrate into a new society, can cause insecurity, anxiety, and a sense of alienation. Mrs. B. said sadly, "for 60 years I lived in the same neighborhood and everyone knew me. When I came here, I suddenly lost my identity. I became anonymous, nobody knew who I am, what I have done all my life. I have become inferior in the world. I am just one old lady out of 300 old people." For many residents the absence of friends often renders the atmosphere in the home as distant and gloomy. Finding new friends and establishing personal relationships is a difficult task, especially in old age. Getting to know and be known requires motivation, risk-taking, confidence, learning, and adaptability, psychological qualities which the elderly resident may require professional help in utilizing for their well-being. The clinical geropsychologist may find here the appropriate ground upon which to help residents utilize their past experience, their social skills, and use ego strength to establish interpersonal and social relationships (Hansson & Carpenter, 1994). Since compatibility renders adjustment easier, the geropsychologist should be involved in decision-making about roommates. At times rearranging the environment may be useful. However, often they have to deal with already existing conflicts, in and between residents, and use them as analytic avenues towards adjustment and emotional security.

7.21.4.3.6 Reframing family relationships

Entering a nursing home necessitates the reformulation of relationships between the residents and their family. This sensitive process is emotionally loaded and may be the ground for deep conflict, as well reciprocal respect and love. The role of the family in the elderly's adjustment and their quality of life in the home is paramount. Relationships may become engulfed in ambivalence and stress, and past family dynamics may become the cornerstone for present conflicts or sound relationships. Although many families experience a heavy burden providing daily care for the older person at home, such stress often continues after the person's institutionalization (Stephens, Crowther, Hobfoll, & Tennenbaum, 1990). There is an ongoing launching process (Lomranz, 1995) in which, in contrast to the stage of adolescence, it is the parent who is being launched. Nevertheless, it bears similar launching characteristics, for example, guilt, ambivalence, letting go, holding on, transfer of responsibility, and mourning (Lomranz, Shmotkin, Eyal, & Zohar, 1996). Tobin (1987) describes children's mixed feelings, guilt and shame coupled with relief, in relocating a parent to a nursing home. Parents, however, may feel frustration stemming from their experience as they in the past shared lodgings with their own parents and grandparents. Although parents recognize the present difference in cohorts, housing arrangements, culture, and lifestyle, some may feel rejected and unwanted, believing that cohabitation would be possible if only desired by their children (Bar-Tur, 1993). Such beliefs may, in response, elicit guilt feelings and hostility in children. Zivoni (1993) found that positive intergenerational relationships had an indirect negative influence on application to a nursing home. Tobin (1987) described the importance of considering institutionalization as a family process. Tobin suggests that there will be a "good" figure (e.g., social worker or intern) satisfying the family's desire for individualized care for the resident, and a "bad" figure (e.g., administration) who could tolerate the family's anger. An elderly person's feeling of disconnection from their family may be detrimental to their mental health. Mutual ambivalence should be worked through. Intergenerational relations and the kind of daily involvement children have with the parent, family visits, and adequate contact with administration are extremely important for the well-being of the elderly and the family. In attending to their clients' problems, clinical geropsychologists sometimes have to involve the children (similar to the case of child therapy). Adult children should also be conceived as part of the social support network and in the role of caregivers, including the difficulties caregivers encounter (Stephens et al., 1990).

To summarize, nursing homes, the effects of institutionalization, and some core issues in a resident's adjustment to a nursing home, have been characterized from a mental health perspective. The elderly living in a nursing home should not be mainly preoccupied with coping and survival. Their quality of life should be the highest possible according to their potential. The nursing home should provide conditions which enhance physical and mental health and promote development and growth. This, however, is not always obtained and hence it is here that adaptational issues and the role and functions of the clinical geropsychologist are dealt with.

For growing numbers of aged people, especially (but not only) those who cannot live independently in the community, adjustment to a nursing home may be a major objective. The above explicated adaptational tasks actually refer to coping with aging processes and institutional effects. These tasks constitute the stage upon which the drama of life for the elderly resident is played out. They may continuously serve as "explosive potentials" as well as issues around which elderly may mask aggression, frustration, and depression. Thus, it is important for the clinical geropsychologist to be aware of them. Diminishment of these factors (e.g., spacial or geographical orientations, social circles) does not necessarily depend on length of residency, but may relate to lifestyle (e.g., a resident who is not mobile enough, or has no contact with the community), coping strategies, and quality of life in the home. For many elderly, life in nursing homes is dull and purposeless. Stripped of external responsibilities and social roles, the importance of the outlined existential components in the daily routine grows unproportionally, consuming physical and mental energy. Yet, at the same time, developmental processes fully operate, preoccupations with health, bodily concerns, life review, family issues, social surroundings, and processes relating to identity and the self. However, these processes may not find direct expression. Conflicts are expressed through the experience and events in daily life, be they tragedies or consumption of food. The clinical geropsychologist must be familiar with these ongoing adaptational tasks, their implications, and the personal meanings attached to them so as to be able to detect and utilize them as avenues to internal life.

If the foregoing may be comprehended in light of existential coping and "social pathology" (Pfeiffer, 1977), the chapter now focuses on more severe psychopathology.

7.21.5 MENTAL DISORDERS IN THE NURSING HOME

The extensive need for psychiatric treatment of nursing home residents has been noted above. Nursing homes report that they are admitting residents who are "sicker" and more frail than in the past. The prevalence of psychiatric behavioral disorders in nursing homes has been estimated to range from 68 to 94% (Grossberg, Hassan, & Szwabo, 1990). Burns et al. (1993) found mental illness among elderly nursing home residents at a rate of 64%; however, only about 4.5% received any mental health treatment in a given one-month period. When they did receive treatment, it was likely to be psychotropic medication only.

Manifestations of psychopathology in residents of long-term care facilities may include complaints of pain, anxieties, physical illness, impulse control problems, personality disorders, deliriums, thought disorders related to dementia, and chronic neurotic or psychotic behaviors. Evaluation of these behaviors and their differential diagnosis is complex and often not performed. Adequate treatment is prevented due to the lack of professional knowledge and facilities, limited resources, and staff. Norris, Snow-Turek, and Blankenship (1995) suggest that the environmental impact of institutionalization, as well as declining health, contributes to somatic and depressive symptomatology, as does frequent napping and use of psychotropic and sleeping medications prescribed (sometimes inappropriately) by general practitioners. The nursing home staff also suffer from such conditions. Everitt, Field, Soumerai, and Auron (1991) note that only minor attention has been focused on the effect on nursing home staff of agitating and disordered residents' behavior which might persist in spite of ongoing pharmacological therapy, although perhaps inappropriately managed. Staff, patients, physicians, and institutions are all leverage points for further intervention to improve the delicate balance between patient behavior, staff distress, and medication use.

7.21.5.1 Prevalence of Selected Syndromes and Interventions

The range of psychopatology in a nursing home is similar to that of the general population. Rovner and Rabins (1985) have divided psychiatric disorders seen in nursing home into three major groups: (i) cognitive disorders (e.g., delirium and dementias), (ii) depression, and (iii) behavioral disorders.

7.21.5.1.1 Dementia

Dementia is thoroughly presented in Chapter 10, this volume; here are highlighted some of their implications in homes for the aged. Estimates of incidence of the disease in individuals who are 80+ range from 10.8 to 47.2% (Gatz, Kasl-Godley, & Karel, 1996), hence its prevalence in many nursing homes is relatively high. As Chapter 10, this volume explicates, dementias appear in various patterns and modes of progression, a fact which carries many implications and difficulties in institutional management and care. Understanding emotions and moods of the older person suffering from dementia, correctly interpreting their behavior, and clarifying the impact of existing care practices are difficult tasks for the staff and pertain to the quality of care the institution is able to provide and the well-being of the demented (Cohen-Mansfield, 1996). Many of the demented elderly in nursing homes suffer from agitation reflected in a range of inappropriate behaviors: repetitive actions (e.g., pacing back and forth, repetition of words); socially inappropriate behavior (e.g., entering someone else's room and handling their belongings, or exposing themself nakedly); and aggressive behavior towards self or others. Often such patients walk out of the institution and cannot find their way back. Different agitating behaviors are associated with different individual characters, organicity, as well as situational characteristics. Such behavior is not only detrimental to the patient and their family, but creates fear and panic in the home where interaction is close and dense. "Healthy" and fearful residents express discontent of not being separated from persons even at early stages of Alzheimer. Each nursing home has its own covert norms and culture which are important for staff to be able to identify it in order to comprehend residents' behavior and reduce their own distress.

At various levels of dementia, aggressive behavior may be associated with poor-quality social interaction (e.g., responding to a roommate's minor invasion of personal space), or result from the patient's unsuccessful effort to interact verbally with their neighbor. Less aggressive behaviors tend to be manifested by persons who suffer from moderate to severe cognitive decline but are in relatively good physical health and under positive environmental conditions promoted by the institution. For some older persons, destructive behaviors may present a form of exercise or stimulation in the face of cognitive deterioration and reduced opportunities for other activities in the home. Various behavioral problems may occur frequently in a home inhabited by individuals suffering from a variety of illnesses, each at various levels of progression. It becomes an extremely difficult task for management to differentiate successfully and separate between such coexisting illnesses among residents.

A broad range of therapeutic functions and interventions are available to the geropsychologist. Proper neuropsychological assessment (see Chapter 7, this volume) is paramount to better understanding the cause of acute behavioral problems and in recommending appropriate treatment and case management. Delirium may be common in nursing homes and differentiation should be made whether or not it results from progressive demetia. The resident with multiple medical problems and receiving many medications may be particularly vulnerable to delirium. It takes special sensitivity to assess some deteriorated behaviors but also to reveal potential abilities and preserved areas. Some patients, for example, who do not respond otherwise, may respond to music even employing their memory. While often residents and staff avoid contact with a demented patient, it is important to provide them with social contact, a comfortable environment, and appropriate stimulation in order to maintain a proper quality of life. Psychotherapeutic interventions should address the different stages of dementia. Dynamic and primarily behavioral orientations ranging from personal to group interventions, including specified groups such as Reality Orientation, have all been used successfully. Other major avenues include working with the family and attending staff. Couples in the nursing home often have to be separated due to the deterioration of one of them, a traumatic event which often requires psychological intervention. The geropsychologist may advise staff regarding issues ranging from environmental safety of the wandering patient to impulse control problems, relevant neuropsychological presentations, and elevating staff distress. The various therapies should be promoted as important components of dignified management, in which the patient's entire life is respected and considered. This may also provide clues to the patient's resources that can to be drawn upon.

7.21.5.1.2 Depression

Depression has been considered the major mental health problem in aging. However, a more cautious approach is being seen. Differentiation in this category is related to issues such as prevalence, etiology, relation to physical illness, biology, and stress, as well as to methodology, screening, and diagnostic approaches (Blazer, Hughes, & George, 1987; Gatz, in press; Katz, in press; Teri, 1991). Affective disorders and depression are elaborated on in Chapter 9, this volume. This disorder in the nursing home setting should be emphasised. The prevalence of depression, its symptoms, or dysphoric mood rank high among residents of nursing homes. They may be subtle and often go unnoticed and untreated leading to excess disability, morbidity, and mortality. While the signs and symptoms are often ascribed to underlying medical problems and advanced age, in fact, some of depression's more prominent characteristics may be observed in many residents: loss of appetite and weight loss; severe fatigue; sleep disturbances; changes in bowel habits and somatization; sadness; feelings of loneliness; generalized lack of interest in life; apathy; increased time spent in bed; avoiding visits; nonparticipation in communal activity; low self-esteem; increased preoccupation with death; and a gloomy evaluation of one's present and future situation. More subtle signs in residents could include: memory problems (pseudodementia); difficulty in making even minor decisions; dreams of being lost and lonely in frightening, desolate places; and crying out for help with no one responding (Pachana, Gallagher-Thompson, & Thompson, 1994). Multiple losses appear in high concentration in nursing homes, perhaps rendering depressive symptoms as almost inevitable in some such institutions. Admission to a nursing home, especially involuntary, transition, and relocation, is often accompanied by an increase in depressive symptoms and lowlife satisfaction (Rovner et al., 1991), although confounding factors such as declining physical health, often the cause for the move, may be involved. Newmann, Engel, and Jensen (1991) have suggested the term depletion syndrome to describe a form of depression commonly observed in older adults, primarily involving lack of interest and feeling that everything is an effort. Blazer, Burchett, Service, & George (1991) term similar symptoms minor depression. These symptoms are often observed among residents and reinforce the search for more subtle signs of depression among nursing home residents. Etiology awaits further differentiation whether such symptoms constitute late-onset disorder, are secondary to residents' deteriorating health or reactive to being institutionalized.

Depressive disorders cause major distress to home and health care personnel. Residents at high risk would include those with a history of depression, poststroke individuals, new residents, those returning from hospitalization or admitted for rehabilitation, and those grieving or having severe adjustment problems. Differentiating between normal and pathological grief is critical. Also, several commonly prescribed medications can have mood-altering side effects, a significant factor when dealing with an institutionalized population which has, perhaps, the highest in intake of medical drugs. Often secondary depressions as manifestations of medical disorders are encountered. In order to provide treatment plans and direct the staff, the geropsychologist should administer diagnostic procedures, via clinical interview, symptom checklist, or more extensive testing. Although in most cases residents are referred to a psychiatrist for medication, the full range of causes for depression should be considered. These could include a variety of intrapsychic and psycho-social aspects, factors in which the geropsychologist's contribution is needed for evaluation and intervention. Effective therapies with depressive people, which also lend themselves well to the nursing setting, are behavior modification, cognitive, and psychodynamic therapies (Gallagher & Thompson, 1982).

7.21.5.1.3 Suicide

Suicide, its epidemiology, risks, and prevention, have been discussed in Chapter 11, this volume. This chapter emphasizes its special danger in the nursing home population. Many nursing homes constitute an assembly of suicide risk factors, as the discussion of depression indicates (Glass & Reed, 1993). Feeling helpless and hopeless, elderly candidates for suicide are less likely to make manipulative or suicidal gestures and they often signal their intentions, which are not always noticed. Some may, however, become unusually quiet and withdrawn. Recognizing the subtle signs of depression may require a high level of professional sensitivity. One clue is giving away valuable personal possessions. In either case, staff are often (it seems too often) "surprised" by the suicidal act.

The impact of suicide in an institutional perspective should be considered. Suicide in a nursing home can have an extreme impact on the residents and the staff. This may also be combated by defensive distancing. Usually it arouses anxiety, anger, and often a feeling of helplessness and inadequacy among those who were involved in the caregiving. Staff and management are often confused as death occurs (e.g., should obituaries be placed in the nursing home, should busing be arranged for funerals, etc.). There is always the threat of "contagion" as one suicide triggers suicidal thoughts or encourages other residents to attempt as well. This produces a threatening atmosphere in which fear of the "next" suicide prevails and is felt by most individuals in the home. At such times, interventions by staff may be crucial. In one nursing home six suicides were witnessed in a period of about two months. The atmosphere in the home became extremely tense. Both staff and residents were very anxious and many expressed guilt, helplessness, and desperation. Inspection revealed feelings of frustration, anger, and despair. A special intervention program was designed, including individual and group discussions in which residents were helped to deal with stressful life events and current obstacles, to ventilate, and were taught self-control and self-relaxation techniques. The psychologist's major task was to identify residents at risk and to provide immediate help for some residents, for example, those who had been friends of the suicidees or witnessed their death. A prevention program was also designed in which staff members were trained to identify signals of threat among residents, and certain security measures and technical devices (e.g., preventing accumulation of drugs, closing "risky" places such as roofs) were taken to prevent future suicidal events.

7.21.5.1.4 Psychotic symptoms and paraphrenia

A variety of delusions, often related to progressive dementia, are seen in patients in nursing homes. More frequent are the paranoid or accusatory behaviors. Late-onset schizophrenics, in contrast to early-onset schizophrenics, have an average life expectancy that seems to exceed that of the regular elderly population (Bienenfeld, 1990). Pharaphrenia, often regarded as late-onset schizophrenia, is usually described as having onset after the age of 60 and entailing paranoid delusions with or without auditory hallucinations, less thought disorder, and less flattening of affect.

Paraphrenia, which has a relatively high incidence among nursing home residents, can also be regarded as a delusional disorder characterized by an isolated delusion and no other symptoms, and with the delusion not necessarily signaling a neurological disorder (American Psychiatric Association, 1994). Delusions in older patients, according to Post (1987), take the form of "unshakable false belief" with remarkably "banal" content. Psychological diathesis for paraphrenia often include premorbid schizoid personality disorder (Pearlson et al., 1989). Traumas earlier in life, such as parental separation, being a refugee, and childlessness, may play a role in increasing vulnerability (Gurian, Wexler, & Baker, 1992), whereas recent stress may trigger the onset of the disorder. Residents who have immigrated from other countries seem susceptible to developing delusional disorders (Ruskin, 1990). Molinari and Chacko (1983) suggest that the development of paranoid symptoms in the elderly patient is usually the result of increased use of projection as a defense against grief or perceived loss of autonomy and control, typical occurrences in nursing homes. Many residents' ideation was often related to past experiences or unresolved conflictual relationships. Mr. G., aged 82, a frail elderly, blamed his wife of adultery since she became involved in the home's activities, while he remained in the room. In an other case, a widowed woman whose two daughters died in the last 10 years and who also suffered from hearing loss and eye sight deterioration, developed a paranoid ideation that her neighbor was stealing from her. These symptoms may defensively protect the resident from painful depression that some individuals experience as a reaction to loss and dependency. Some researchers have reported that hearing loss is associated with late-onset schizophrenia or paraphrenia and frequently among dementia patients with paranoid symptoms (Gurian et al., 1992). Paranoid symptoms may thus develop as a result of mental deterioration reflecting prethreshold organic brain change, sometimes in order to fill the gap created by impaired memory (Gatz, et al., 1996).

Late-onset psychotic symptoms often have an organic etiology. Therefore, a thorough medical and laboratory evaluation, together with a psychological one, should be obtained. A useful rule of thumb when dealing with psychotic symptoms in the nursing home is to ask to what degree these symptoms are disturbing to the patient or to the environment. Often such states are best treated nonchemically, late-onset schizophrenia does have more preservation of personality and less formal thought disorder then early-onset schizophrenia. If psychotic symptoms are disturbing, antipsychotic medication and ongoing psychiatric involvement is certainly called for. Case management interventions, such as encouraging the patient to remove from people or situations which stimulate the paranoid ideation, could be helpful. The role of the geropsychologist to could be to establish an alliance with the patient (Fried & Agassi, 1976), thus encouraging them to share thoughts about present and past experiences. When such communication can be established, the patient becomes less anxious and an ongoing treatment plan, with the consulting psychiatrist at the home, can be established.

7.21.5.1.5 Personality disorders

Personality disorders are discussed in Chapter 12, this volume, This discussion is limited to highlighting aspects relevant to nursing homes. Given the residents' advanced age, difficulties in diagnosis become apparent. Properly diagnosing personality disorders is further encumbered by the impact of the institutional environment, changes in cognitive processes, sorting out chronic from acute behaviors, and difficulties in obtaining history. A lifetime pattern of pathological interpersonal relationships, the present old-age experience of losses, and institutionalizational rules, all further promote regressive psychological functioning and may elicit primitive defenses such as splitting, all of which gain a special intense quality in an environment with multiple caregivers. Personality disorders are often seen in conjunction with other disorders, in particular major or masked depressions, frequent in nursing homes. Residents with personality disorders are especially ill-equipped to cope with the stress of institutionalization. Many of the "difficult" or "uncooperative" residents in a nursing home can be diagnosed as personality disorders, sometimes coupled with cognitive decline. Such residents may manifest inappropriate emotional responses or inconsistent control of impulse behavior, including aggression and violence. Sadavoy and Fogel (1992) suggest that these patients tend to represent a vulnerable personality that becomes increasingly less adaptive with new stressful events in old age due to eight critical age-specific stressors: interpersonal loss, physical disability, loss of external manifestations of the self (beauty, strength), loss of role, loss of defensive outlets; forced reliance on caretakers, confrontation with death; and conflict over the wish to live vs. the wish to die. Another major loss for such residents is the loss of resources of narcissistic gratification from others. These difficulties are often manifested in distorted ways such as self-perception oblivious to one's impact. This affects interaction with other residents and staff, and may lead to constant conflict with management. Difficulties in these individuals often result from the state in which they have to be dependent on others and to rely on them to supply their needs. They may fight for independence and autonomy in order to maintain their self-esteem by manipulating the staff, by refusing to obey rules, and acting out their anxieties and conflicts.

In spite of the difficulties with such patients, they may benefit from regular psychotherapeutic contact and are able to establish an alliance with the therapist. The relationship with the psychotherapist itself may gratify narcissistic needs which otherwise might have been expressed destructively. Work with the patient's family and staff caretakers is also indicated to introduce possible case management procedures shielding such a patient from stress or encouraging real and/or perceived autonomy and control (Perlmuter & Monty, 1979).

Although the major symtomatology has been outlined, it should be emphasized that the more "benign" disturbances and neurotic behaviors do not receive due attention, as if neuroticism disappears in old age and the elderly suffer only from cognitive difficulties, dementias, and psychosis. Reality is completely different; neurotic behavior and existential concerns are "there to stay," can be treated (including with psychotherapy), and present a major component in the mental health of the elderly in general and in nursing homes in particular. Other disturbances prevailing in nursing homes, and not discussed due to lack of space, include anxiety and somatoform disorders (Stanley and Beck, this vol.), drug abuse (Blow, this vol.), sleep disorders (Ancoli-Israel, this vol.), impulse control wandering, behavioral problems, family issues, further neurotic and psychotic disturbances, as well as surrogate decision-making for nursing home residents. Having emphasized that health problems do not receive adequate treatment, a comprehensive treatment model is presented to address all the explicated mental health issues discussed.

7.21.6 A CLINICAL GEROPSYCHOLOGICAL SERVICE IN NURSING HOMES: A PROPOSED MODEL

A geropsychological clinic operating in a nursing home in Isreal is described (Lomranz, 1991) and presented as a model clinic.

7.21.6.1 Setting and Clientele

The clinic operates within a nursing home housing a population of 750 residents. A psychiatrist serves as consultant. The elderly residents range from those functioning independently to those needing constant nursing care. The clinic is a recognized internship center for clinical psychology interns and is associated with the Tel Aviv University's Herczeg Institute on Aging. The target clientele consists of two main categories: the residents themselves and associated significant figures, mainly family, and the professional and paraprofessional staff. The clinic's framework includes regular staff meetings, case conferences, supervision, study groups, and seminars, as well as participation in many of the nursing home conferences, including referral conferences, admission committees, and meetings planning activities for residents.

7.21.6.2 Orientation and Philosophy

The philosophy constitutes the *zeitgeist* which prevails in the clinic and should be expressed in interaction with clientele, above and beyond the "professional approach." It is reflected in: (i) a dual focus on the image of a person, a Bo-psycho-social holistic view (Engel, 1977) embedded in a humanistic approach and respect for personal dignity, and a life-span developmental psychology orientation (P. Baltes & M. Baltes, 1993). The two orientations are eminently compatible. (ii) Comprehension of the environment and the significance of person/environment interaction; (iii) Aim: to improve mental health and upgrade the quality of life; (iv) Methods: The service adheres to a dynamic theoretical approach based on elaborations of clinical adult developmental theory (Nemiroff & Colarusso, 1990) and other eclectic clinical techniques of diagnosis and treatment. It has often been observed that mental health problems in nursing homes may go unnoticed for long periods of time. It is often only when a resident "becomes a nuisance" that they are dealt with. Early detection may improve the utility of treatment. It is therefore crucial that the service adheres to outreach, prevention, and community orientations.

7.21.6.3 Methods

The eclectic approach is tailored to the specific needs of the client. These approaches include dynamic, cognitive, and behavior modification, group methods, family and milieu systems, existential therapy, organizational, educational, and community approaches. Specific techniques found useful with the elderly are employed, including life review therapy, reminisence groups (Haight & Webster, 1995), family counseling (Brink, 1979), and educational programs and training (Garrison, 1978). These are applied to individuals, families, groups, community, staff, and interdisciplinary networks. Group work (e.g., psychotherapy, family, task groups, life review) is a major methodological component (MacLennan, Shura, & Weiner, 1988). Intervention are geared to eliminate psychopathology as well as preventive work to increase clients' sense of control and hopefulness about change. Reserve capacities are utilized, based on selection, optimization, and compensation (Baltes & Baltes, 1993; Ryff, 1989). Considerable attention is paid to assessment and diagnostics (Storandt, Siegler, & Elias, 1978). Existing diagnostic tools are adapted or modified, and specialized tools are developed in cooperation with the University Herczeg Institute on Aging. Thus, traditional and nontraditional approaches for intervention and assessment are employed. The psychologists work in cooperation with social workers, occupational, art- and physiotherapists. Special attention is given to psychosoma interaction, and ongoing communication is maintained with the medical and paramedical staff. Regular contact is held with the "Home mother," the caregivers, and technical departments (e.g., maintenance, cleaning, kitchen). Informal contact and interaction (discussions in the elevator, garden, etc.) are part of the approach and highly valued. All these activities also contribute to the integration of the clinic as an integral part of the nursing home.

7.21.6.4 Applications

Most referrals originate from interdisciplinary staff meetings, medical and social services, or individuals recommending neighbors. A minority are self-refered. Three principles of psychological interventions of a curative, preventive or palliative nature are categorized and for the sake of convenience, termed: (i) "treatment," basically consisting of a direct, short-term, or long-term systematic psychotherapeutic approach applied to different kinds of psychopathologies; (ii) "consultation," attending transitional, normative, or situational crises. This is mostly accomplished directly, but often indirectly (e.g., instructing a nurse, neighbor): short consultation or direction of other staff are central here; (iii) "prevention," consisting of two main activities of working with residents or staff on problematic issues or risk populations (e.g., groups work with isolated residents just before major holidays, or tackling staff problems of burnout) or of educational activities aimed at enriching the residents or furthering the professional development of the staff (e.g., lectures to residents on mental health or to staff on psycholpathology).

Thus, the psychological services in the nursing home comprises seven domains with their respective working goals of mental health.

7.21.6.4.1 Preadmission screening

Every applicant is interviewed and assessed to obtain information on cognitive as well as affective functioning and status. Thus, the service can be advise management in decisions to accept or reject an applicant. For those accepted, preadmission screening may be paramount in certifying the type of care and living facilities that the elderly requires (Smyer, 1989). While most people admitted to a nursing home have mental concerns and some physical problems, it is generally the latter which are documented and communicated to the staff, while mental or behavioral problems are rarely discussed professionally. At times, there is a tendency for the family and the older client to withhold information regarding deterioration of mental state. Such clients, once admitted, exhibit serious adjustment difficulty and, moreover, their cognitively impaired as well as affective state may deteriorate more rapidly. The psychologist can support the client and the family and can help reduce their initial anxiety, obtain their cooperation in assessing adequately the client and as a result prevent unnecessary misery and rapid decline in mental health.

7.21.6.4.2 Follow-up services

Working on the basis of data obtained in prescreening, the psychologist is later involved in assessing the follow-up of the new resident. Some residents need supportive sessions or crisis intervention, short-term therapy, focused on issues of separation and mourning over the losses they experience at the early phases of their transition to the nursing home. Others may be directed to task groups or activities in the home. The service conducts open-ended adjustment groups which focus on relocation effects during the first three to six months, a group in which every newcomer participates for at least several sessions.

7.21.6.4.3 Severe psychopathology

Here the clinic functions as any other psychiatric setting. Patients are refered and diagnosed, and treatment is planed and carried out. Often, combined psychopharmacological and psychological treatment is administered. Individual psychotherapy is increasingly being requested by residents.

7.21.6.4.4 Family interventions

A resident's family always occupies them in practice or in thought. The elderly person usually arrives at the nursing home accompanied by family members, with the adult children formally assuming "filial" responsibility, acting as "parents" as they relate to their parent and deal with staff and management. This role reversal is often likely to heighten the anxieties and difficulties of all parties concerned: children, parents, and staff. As some residents experience separation anxieties and relocation symptoms are manifested, the anxious, or guilt ridden, children may respond by engaging in acting-out behaviors. They may cause inconvenience, aggravate staff, and exhibit overdo concern. Parents, in turn, increase their fears and guilt by complaining, crying, expressing helplessness, and despair. This was the case with Mr. R., aged 88, who, prior to entering the home was functioning well, spending his time painting and sculpturing. He was forced to move to the nursing home after falling and became unable to take care of himself. He was the father of two devoted sons who encouraged him and helped him move to the home. Mr. R. seemed quiet and reserved in the admission interview. However, as soon as his sons left he became extremely anxious and restless. During his first week in the home he spent most of the day wandering around the phone box crying and calling his sons, asking them to visit. He nagged staff and other passers-by near the phone box to call his sons. His sons became concerned and paid visits a few times a day. Family sessions were held in which the children comprehended the father's separation anxieties and his intensive need for support. The sons were encouraged to talk about their own anxieties and work through their ambivalence at "launching" their father. The psychologist presented a treatment plan for the father with guidelines for the family and the nursing staff to help the father settle down and slowly shift towards self-control instead of enacting his need to control his sons. He gradually learned how to master his anxieties, his sadness declined, and his phone calls ceased.

Mr. G., 80-years old, lived in the nursing home for five years. His relationship with his only son was completely cut off, each accusing the other of ill-treating the mother/wife who passed away prior to Mr. G's move to the home. On memorial day each would come to the cemetery at a different hour. Mr. G. appeared to be well adjusted in the home until he developed a prostrate condition and feared he would die. At that point he began to long for his son who, stubbornly, refused to see him. The son had 20 hours of telephone discussions with one of the psychologists, during which he voiced his anger, discussed the role his mother played in his life, and his hate and ambivalence to his father. Only afterwards was a meeting arranged in which the two brought flowers to the mother's grave and joint treatment began.

7.21.6.4.5 From education to psychotherapy

Extending educational programs to residents and their families provides a channel leading residents to self-development. Psychological education is often a condition for various ethnic, economic, and less-educated residents to become utilizers of the psychological services.

Many elderly suffering in nursing homes may find it difficult to discuss personal issues and emotional problems with others, will not take the initiative to obtain psychological help, and may also refuse it when offered. One way to combat such difficulties is through offering relevant information, developing the proper atmosphere, and providing opportunities to meet therapists. Different psychologists and interns of the service provide a monthly lecture, open to residents, their families, and staff, on various aspects of the aging process, general psychology and adjustment issues in nursing homes. The psychologist then leads a discussion encouraging the audience to ask questions and to share ideas, thoughts, and feelings.

Mrs. J. approached the psychologist after a lecture on intergenerational relationships, seeking advice for problems her granddaugther has with her father. In the discussion she revealed her intense identification with the granddaughter voicing anger at her son. This became a basis for her visits to the service. She then focused on personal problems and remained in psychotherapy for eight months. Mrs. W., a highly educated 92-year-old, wished to continue the lecture on "successful aging" with the "young professor" (professional status being usually important, and overrated by elderly). This provided her with the opportunity to gain respect for her own knowledge and experience and eventually led to an extended and structured life review, after which she became more accepting of her present condition and learned new social skills. Obstacles in approaching the psychologist also reside in prejudice and stigmas about mental care, common in the older population. Public lectures, or special workshops (e.g., in communication skills, memory techniques) help the elderly, prospective client reduce anxieties and shame. Such activities, to most of which family members are also invited, may also serve as a vehicle of outreach to enhance constructive family involvement.

7.21.6.4.6 Working with nursing home staff

This is a primary goal in the work of the clinic. The clinic administers intervention programs aimed at reducing staff distress, professional upgrading, promoting team work (e.g., to eliminate stress between workers in the kitchen), assisting conflict resolution between various teams and between them and management, and preventing burnout.

Nursing homes often have high turnover rates and low staff morale, resulting from work pressures in dealing with threatening issues (aging, loss, illness, and death), distorted perceptions, and low intrinsic and extrinsic rewards. Psychologists in the service work with the interdisciplinary teams providing guidance, information, knowledge, and help in management of residents (e.g., how to address residents' hostile behaviors towards them), in coping with personal problems, and symptoms of burnout (increased fatigue, apathy, etc.). Workshops are conducted on improving interpersonal communication among the staff aiding managers to establish positive reinforcement techniques (Sbordone & Sterman, 1983), improving problem-solving on team building, and preventing burnout. Working educationally with different ranks of staff, the psychologist also conducts discussions, lectures, and case conferences with the various teams (e.g., medical, maintenance workers). Most interventions are based on short-term programs of two to six sessions.

The geropsychologist should project an independent, often "neutral," professional position in the home, thus promoting authority and the ability to work successfully with the various teams, management, and residents. The clinic has witnessed turnovers and shifts in staff roles as well as changes of management often resulting in unclarity and uncertainty as to structure and management. In one such instance staff had major difficulties adjusting to a transition period between managers. Discussions with the psychologist, working as an organizational consultant, revealed an accumulation of covert anger and coalitions between different team members detrimental to ongoing work. Often, in meetings, issues concerning complains about residents reveal conflicts between different teams of the staff. In another case, a nursing team became almost ineffective. It turned out that the team was understaffed, frustrated by hard work and lack of appreciation and recognition by management, and rapidly revealed burnout syptomatology. Group discussions combined with private sessions helped them release their feelings, work through some of the communication patterns with management, and address their complaints effectively. Some of the clinic's staff are also called for consultation to other nursing homes in the vicinity.

7.21.6.4.7 A university clinic

Coordinating links with the university's institute of aging and the nursing home, teaching and supervising students and interns, and cooperating in research are all part and parcel of the clinic. The staff includes postgraduate clinical psychologists who work as interns in the nursing homes, and provide supervision to undergraduate and graduate students of clinical psychology. Undergraduate students participate in a special practicum program involving them in activities which may range from friendly visits to more structured intervention, participation in group work, and providing lectures to the residents. Such liaisons with academic settings are beneficial to all parties involved and upgrade the quality of the home (Smyer & Garfein, 1988). They also encourage young students and interns to choose aging as their field of specialization (Kahana, 1986).

This section concludes with some general evaluative remarks. During two years of operation, residents have changed their attitudes to psychological services. They became less skeptic, have come to recognize the importance of the clinic, and make greater use of its services. Experience suggests the recommendation that as geropsychologists, even intermediately until clinics are set up, working as individuals in nursing homes, they should: (i) establish their position as consultants in a variety of roles; (ii) dwell on diagnostics and assessment; (iii) become major referal directors; (iv) operate as coordinators between teams; (v) be clinical-community oriented; (vi) advance milieu treatment; (vii) assert their impact on policy-making in the institute; (viii) plan and utilize interdisciplinary interventions; (ix) be liberal in using eclectic, traditional, as well as untraditional, intervention approaches, including psychotherapy; and (x) invest in educational programs and systematically accumulating knowledge through documentation and research.

The possibilities of psychotherapy in nursing homes should be emphasized as a challenge for every clinical psychologist. The goals of psychotherapy should be modified and theoretically they should consider gerontology, adult developmental processes, cognitive and medical losses and the effects of institutionalization, as well as clinical methodology. The dialectics between "case specificity" and "age specificity" have to be analyzed. Short-term treatment is often required (Brink, 1979; Gallagher & Thompson, 1982), and a relational approach to transference seems conducive (Frankel, 1995). In long-term therapy, sessions could be of short duration and may be conducted in the residents' personal environment (their room, or in the ward). Long-term psychotherapy often provides the resident with continuity assuring them of the therapist's availability as a secure base (Bowlby, 1980). Many problems of the aged person are fit for intrapsychic and interpersonal exploration and lend themselves to life review, development, and growth. While psychotherapy is always tailored to the specific case, its possible gains with the aged are (in the proper perspective) as unlimited as they are with younger populations. Psychotherapy should be considered as a viable option for the elderly (Shmotkin, Eyal, & Lomranz, 1989). The pleasure and growth in working with the suitable aged can be tremendously gratifying for all parties.

7.21.7 FUTURE PROSPECTS

There is undoubtedly an increasing need for mental health services in nursing homes. As the nursing home industry develops, this need intensively grows. Existing mental health facilities need to be expanded and improved, urgently, to answer neglected and increasing needs. Unfortunately, psychologists, not to mention geropsychological clinics, rarely are found in nursing homes. Also, the nursing home setting is ill-prepared to accept and employ psychologists. The absence of systematic assessment procedures, diagnosis and evaluation, consultations, therapy, and other appropriate interventions have a high cost. Unfortunately, there is a pronounced shortage of psychologists in gerontological clinical work in general (Gatz, 1995; Gatz et al., 1985). Clinical psychology as a discipline is still largely child-oriented and continues to reflect "professional ageism" (Butler & Lewis, 1982), especially with respect to nursing homes. The many misconceptions about the the older person (e.g., lack of energy, motivation, rigidity, and resistance to change) still remain after many decades and affect the "reluctant psychologist" who is unwilling to work with the elderly. Working with the elderly still seems to be rated by colleagues as having low professional status (Knight, Reinhart, & Field, 1982), all the more so in a nursing home. Psychologists may also tend to shrink from interdisciplinary collaboration and conflict (e.g., with psychiatrist, social workers, or other paraprofessionals). Working in a nursing home is often regarded as depressing and difficult since illness and death, helplessness, and hopelessness are confronted continuously. What then are the future prospects?

To meet the crucial challenge, a broader perspective should be adopted which associates geropsychology more strongly with clinical psychology at large and considers policy issues (Kane & Kane, 1990). Basic changes are recommended as stated in the following: (i) the discipline of clinical psychology has to further modify its developmental approach to include adulthood and aging; (ii) theory construction in clinical gerontology while thoroughly based on gerontology also needs to further integrate prevalent clinical theory (e.g., object relations); (iii) clinical methodology in geropsychology, on the aforementioned basis, should be eclectic and modified in goals and methods to fit the elderly population; (iv) policy should be further planned and policy makers have to present, perhaps more aggressively, the damage to nursing homes in cost-effective terms and develop reimbursement systems; (v) academic education and training has to be expanded intensively to include clinical geropsychology; (vi) governmental regulations should include the request for in-home psychological services in nursing homes as obligatory; and (vii) nursing homes should become academic-associated institutions, and clinics, as certified training placements and research units, should operate in each.

The major goal of the clinical gerontologist in nursing homes should be to contribute to a fundamental change which would render the various institutions as authentic "homes" in which residents could actualize their potentials for positive mental health, live with dignity, enhance their well-being, and live creatively. For that purpose, which to a certain extent will determine the kind of society that is built, the discipline of psychology, on its various domains, is expected to mobilize itself to change and meet that challenge.

7.22.1 INTRODUCTION

Family care of disabled older people has emerged as one of the most important clinical and social issues in an aging society. Historically the family has been the main source of help to the elderly, but in previous eras when most people did not survive to old age, families' involvement in providing care to parents or grandparents tended to be limited and brief. The demographic revolution of the late twentieth century has resulted in more people surviving to ages when rates of disability are high. As a result, increasing numbers of older people need at least some help to manage activities of daily living. The most frequent source of that help is the family. Providing care to a disabled elder poses considerable challenges to the family. Care needs may place physical strain on caregivers or may impinge on already full schedules of work and family responsibilities. The dependency of a spouse or parent can also intensify long-standing family problems, or overwhelm the psychological resources of caregivers. Formal social and health services can reduce the burden of care on families, but can also introduce new strains or problems. Clinicians can make timely and effective interventions to mobilize the family's resources, address family conflict, and maximize the ability of both the family and the disabled older person to meet the challenge of disability.

This chapter will present an overview of research on family caregiving and clinical interventions to relieve strain on the family. The chapter begins by introducing basic concepts to provide a foundation for examining research findings and clinical approaches. Three main areas of research on family caregiving are reviewed: how family relationships set the context for caregiving and in turn are affected by it, role conflict in caregiving, particularly, between employment and caregiving, and how the stresses of caregiving influence mental and physical health. The chapter concludes by examining clinical interventions and services designed to relieve stress on families and research on their effectiveness.

7.22.2 BASIC ISSUES IN FAMILY CAREGIVING

In this section the emergence of family caregiving as a major social issue is reviewed, and four issues are presented which guide understanding of this phenomenon: (i) caregiving as a career; (ii) stress proliferation and containment; (iii) the family context of caregiving; and (iv) the care recipient's perspective.

Caregiving has become an important concern because of the convergence of several social trends. The developed countries of the world are aging societies, that is, increasing proportions of their populations are 65 years of age and older. In fact, the fastest growing segment of the population is the "oldest old," people aged 80 years or over (Kinsella & Taeuber, 1993). Most older people live independently with few or no physical limitations, but the likelihood of disability increases with advancing age. By age 85 years, 60% of the population has at least some degree of disability which requires regular, ongoing assistance (Zarit, Johansson, & Berg, 1995). Among 85-year-olds with no disabilities, approximately 30% develop problems over the next two years, and another 30% do so in the following two years. Clearly, there is a growing risk of disability at very advanced ages.

How the aging of the population leads to increased risk of disability can be illustrated by the example of Alzheimer's disease. Although this disease can occur in people as young as 40 years of age, the greatest risk of incidence is after 75 (Johansson & Zarit, 1995; Jorm, Kortem, & Henderson, 1987; Kokman, Chandra, & Schoenberg, 1988). When most people in a society did not survive to 65, let alone 75 or 85, a disease such as Alzheimer's had a trivial impact. The dementia syndrome has been described since antiquity, but it has only assumed importance since the 1950s as large numbers of people have survived to the ages of greatest risk. For people surviving to their mid-80s, the cumulative risk of developing dementia due to any cause before death may be as high as 47% (Johansson & Zarit, 1995). The result is that many older people require considerable assistance for a period of time before their death.

Extension of the average life span has meant that people have, on average, a longer period of active life. They are able to live independently into their 70s, 80s, and even in some cases 90s. But the factors which have led to improved life expectancy, better medical care and improved public health, may also be contributing to a prolonging of the period of disability at the end of life. The Expansion of Morbidity Hypothesis (Cassel, Rudberg, & Olshansky, 1992) posits that people now survive longer with chronic diseases and with greater amounts of disability. While unequivocal data to support this hypothesis are not available, it is widely apparent that people with severe disabilities can survive for long periods of time. To cite one example, 50% of a sample of dementia patients (with varying diagnoses) were alive 11 years after the first onset of symptoms, and just under 40% survived more than 14 years (Aneshensel, Pearlin, Mullan, Zarit, & Whitlatch, 1995). This long duration of morbidity is an important factor in the heavy caregiver burden placed on families and society.

The net result of these trends is that more older people need help for longer periods of time than ever before. At the same time, families' resources for providing help have probably diminished somewhat. The most likely person to give assistance is a surviving husband or wife, but that person will also usually be elderly and may have disabilities which limit the amount or type of help that can be provided. Because of historic trends toward smaller family size, there are, on average, fewer children available to share the care of a disabled parent. Daughters and daughters-in-law have previously provided much of the assistance to elders, but with women's participation in the workforce, fewer full-time homemakers are available to take on caregiving responsibilities. Finally, historically high divorce rates in many Western countries weaken family ties and may diminish the amount of help available when a parent becomes disabled. Divorce in the parents' generation may have left strained or weakened ties with children, while divorce among children may result in their having fewer resources to commit to the care of an aging parent (Webster & Herzog, 1995).

These sociodemographic trends provide the context for caregiving. Four important concepts set the stage for discussion of research and clinical interventions: (i) caregiving as an ongoing, evolving process; (ii) stress proliferation and containment in caregiving; (iii) family systems theory; and (iv) the importance of addressing the needs of both caregiver and care recipient.

7.22.3 CAREGIVING AS AN ONGOING PROCESS: CAREERS OF CAREGIVERS

Caregiving involves an ongoing process, in which problems change and the caregiver's perceptions of problems also evolve. Just as the care recipient's disorder can span several years, caregiving also has a long duration. The tendency for studies to capture caregivers only at one point in time often obscures the temporal structure of what has come before and what lies ahead.

To describe this process, Pearlin (1993) has introduced the construct of caregiving careers, that is, that caregiving is a role involving certain predictable expectations and transitions. Using findings from a longitudinal study of caregivers of dementia patients (Aneshensel et al., 1995; Pearlin, 1993), Pearlin and his colleagues suggest three distinct phases in a caregiver's career. First is the period of role acquisition, during which caregivers recognize the growing disability in their relative and make the decision to take on the caregiving role. In progressive disorders such as dementia, this recognition develops gradually. Families frequently will ignore the growing signs of disability or hope that their relative will snap out of it and return to normal. A physician's diagnosis or a critical event, such as the patient getting lost or mishandling a sum of money, often changes how the family views the situation, although caregivers may still fluctuate in their acknowledgment of disability and their relative's need for assistance. The tendency in dementing illnesses for patients to deny their problems or disabilities, especially as the disease progresses (e.g., Kaszniak, 1996), undoubtedly contributes to families' ambivalence in recognizing the disorder and taking on care responsibilities.

The second phase in the caregiving career is role enactment, during which caregivers provide regular, ongoing assistance to their relative. Role enactment includes providing care to people in the home, and also in institutional settings. As we will see below, caregiving does not end at the institution's door. Families remain involved in care. While placement relieves some stresses, it introduces other problems and challenges for the family (Zarit & Whitlatch, 1992). The transition from home to institution may also be one of the most stressful times for families. Most of the available research addresses the period of role enactment, especially concerning caregivers providing care in the home.

The third phase in caregiving is disengagement, which is marked by the patient's death. Although psychological disengagement sometimes occurs sooner, death of the patient is a critical turning point that has complex effects on caregivers. Death of the patient is frequently welcomed when it brings release from a long, painful or deteriorated condition. Yet it also forces caregivers to re-examine and reorient their lives. Grief follows a predictable course, with symptoms greatest following the patient's death, and then gradually diminishing, although some caregivers remain distressed for a sustained period of time (Aneshensel et al., 1995).

Caregiving, then, should not be viewed as a static event that takes place for a limited duration of time. It is an ongoing process with some predictable demands and transitions. The pressures on the family depend to some extent on the phase of caregiving. Likewise, the type of clinical intervention will depend on whether caregivers are assuming the role, are in the midst of performing extensive caregiving activities, or are trying to reconstitute their lives following their relative's death. (For a description of varying clinical interventions over the full course of caregiving, see Zarit & Zarit, in press.)

7.22.4 CAREGIVING STRESS: PROCESSES OF PROLIFERATION AND CONTAINMENT

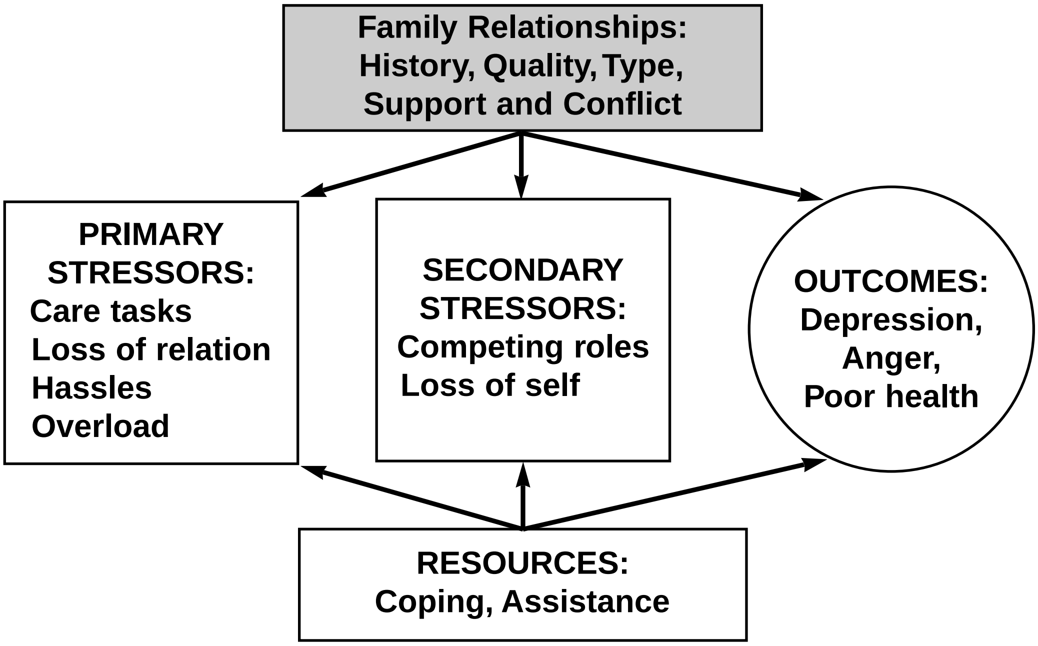
Caregiving has generally been viewed from the perspective of stress theory. Stressors represent all of the conditions, experiences, and activities that are problematic for people by thwarting their efforts, threatening their well-being, and disrupting otherwise stable systems (Aneshensel et al., 1995; Pearlin, Mullan, Semple, & Skaff, 1990). Chronic stress creates a state of perpetual arousal that taxes the individual's usual ability to adapt to the environment, and so compromises their ability to reach sought-after goals (Lazarus & Folkman, 1984).

A specific model is used to guide exploration of caregiving. The stress process model, developed by Pearlin and his colleagues (Aneshensel et al., 1995; Pearlin et al., 1990) has been used to guide a major longitudinal investigation of caregivers of dementia patients. This model identifies three major components in caregivers' experiences: primary stressors, secondary stressors and outcomes (see Figure 1). Primary stressors evolve directly from the needs of the patient and represent the actual tasks of caregiving. These stressors are called primary because they are intimately associated with the root of the stress, namely, the chronic disabilities of the care recipient (Pearlin et al., 1990). Examples of primary stressors are behavioral problems, memory problems, and difficulties carrying out activities of daily living (ADLs).

Coupled with the objective conditions of caregiving are the caregiver's subjective appraisals of the memory problems, behavioral disturbances, and ADL deficits. Some primary stressors are more problematic or challenging than others and so can affect coping skills and erode caregiver self-efficacy (Kinney & Stephens, 1989). Pearlin et al. (1990) specifically identify feelings of overload and role captivity, that is, a sense of being trapped in the caregiving role, as primary subjective stressors. They also propose that the caregiver's sense of loss of the relationship with the care recipient should be considered a primary stressor.

Evolving out of the primary stressors are the secondary stressors. Although termed secondary, these stressors are of no less importance. They represent the way in which primary stressors encroach upon and disrupt other areas of the caregiver's life, and thus are more variable and individual in their manifestation. Secondary stressors include family conflict, financial strain (e.g., reduced financial resources as a result of caregiving) and work conflict. They also involve psychological dimensions, such as diminished self-esteem and a feeling of loss of self, that the caregiver's identity has been absorbed totally in the caregiving role (Skaff & Pearlin, 1992).

Long-term exposure to stressors can produce a variety of physiological and psychological changes, or what are termed outcomes in the



Family Relationships: History, Quality, Type, Support and Conflict
PRIMARY STRESSORS: Care tasks Loss of relation Hassles Overload
SECONDARY STRESSORS: Competing roles Loss of self
OUTCOMES: Depression, Anger, Poor health
RESOURCES: Coping, Assistance

Figure 1 A model of caregiving stress and family relationships.

stress process model. Among the outcomes that have been studied are depression, anger, well-being and a variety of indicators of health. These outcomes occur as chronic stress which results in disruptions of people's homeostatic mechanisms that overwhelm their coping resources.

Stressors, however, do not have a fixed or constant effect on outcomes. The caregiving literature has documented considerable variability in how caregivers adapt to similar circumstances (e.g., Aneshensel et al., 1995; Haley, Levine, Brown, & Bartolucci, 1987; Wright, Clipp, & George, 1993; Zarit, Todd, & Zarit, 1986). The relation of stressors and outcomes is described in the stress process model in terms of two mechanisms: stress proliferation and stress containment (Aneshensel et al., 1995). Stress proliferation describes how the stressors involved in caregiving infiltrate and disrupt other areas of the caregiver's life. Primary stressors lead in varying degrees to secondary stressors, which in combination lead to negative outcomes. Stress proliferation is greatest when caregivers are assisting someone with higher levels of behavior problems and when there is a greater subjective effect of these stressors, for example, when caregivers feel overwhelmed or trapped in their role (Aneshensel et al., 1995; Haley et al., 1987; Zarit et al., 1986). Stress containment, in turn, describes how the caregiver's use of resources may limit or circumscribe the effects of stressors. How caregivers cope with specific problems as well as the amount of social and financial resources available to them can protect them from some of the adverse effects of stress.

The outcome of a particular configuration of caregiving stressors is variable. The amount of variance in caregiver outcomes, such as depression, that is accounted for by any particular stressor, for example, the patient's behavior problems or the amount of family conflict, is statistically significant but relatively modest (Aneshensel et al., 1995). Instead, outcomes depend on the extent of proliferation or containment.

The implications of this framework for clinical intervention are twofold. First, clinicians need to assess which primary and secondary stressors are present in a given situation. Caregiving and caregivers' resources are sufficiently varied so that the constellation of problems and stressors will differ considerably from one family to another. Rather than assuming that a constellation of stressors will be overwhelming or that a caregiver will necessarily experience work or family conflict, clinicians need to conduct an assessment to identify the specific proliferation of stress in the caregiver's life. Second, the goal of clinical interventions is to reduce sources of stress proliferation and enhance the caregiver's resources that lead to containment. Although it may not be possible to change the patient's underlying disability or to alter the primary stressors on caregivers, interventions can modify their impact on the caregiver's life (Whitlatch, Zarit, & von Eye, 1991). In the sections below, research is highlighted which suggests which factors are associated with greater or less stress for family caregivers and which may be amenable to clinical intervention.

7.22.5 CAREGIVING IN A FAMILY CONTEXT

Stress theory is useful for characterizing the problems and challenges faced by caregivers, but it does not take into account the specific family context in which caregiving occurs. The relationship between caregiver and care recipient and their relationships with other family members should be considered. A family systems perspective focuses on what roles and functions a person performed within the family as well as the quality of these relationships (Zarit, Orr, & Zarit, 1985). Because of illness and disability, the care recipient can no longer perform certain activities and functions for the family. A spouse caregiver, for example, may experience the loss of a confidant and sexual partner, and may have to take over activities that his/her spouse previously performed in the household. Besides these specific losses, care recipients and caregivers have varying amounts of prestige and influence in the family, which affects how much help and assistance other people will provide. Children who view a caregiving mother as extremely competent may not view her as needing help. Conversely, a mother who is viewed as needy or lacking competency may get too much help or a mixture of criticism and assistance. Caregiving can also reawaken or intensify long-standing conflicts in the family.

7.22.6 THE PERSPECTIVE OF THE CARE RECIPIENT

Lost in much of the caregiving literature is the perspective of the person receiving care. In part, this omission is due to the extensive focus on providing care to people with dementia, who lose the ability to report their experiences reliably as the disease progresses. This exclusion, however, means that the care recipient's perspective often is overlooked. Care recipients can continue to provide some types of help, assistance, or comfort to the caregiver, even in cases of moderate to severe dementia. The care recipient's well-being and needs should be considered along with the caregiver's, in decisions about living arrangements and care. It is important to consider whose interests are being represented when making a clinical intervention. What is good for the family may, in some circumstances, not be in the patient's best interest. The clearest example is nursing home placement, which relieves strain on families but puts the dementia patient at risk for a variety of adverse outcomes, including an increased risk of mortality (Aneshensel et al., 1995). Though often omitted from research, the patient's perspective needs to be incorporated consistently into clinical intervention.

7.22.7 RESEARCH ON FAMILY CAREGIVING

The following review of the research literature focuses on the stress process and family relationships. It starts by emphasizing caregiving in its family context, and the relationships of caregiver and care recipient to one another and to other family members. One of the main secondary stressors, is then considered, that is, when there is strain or conflict between caregiving and employment. Finally, consideration is given to what is known about the effects of caregiving on physical and mental health and some of the correlates of negative outcomes.

7.22.8 CAREGIVING AND FAMILY RELATIONSHIPS

In this section, attention is focused on caregivers and their family relationships. Two primary themes underlie the organization of this section. First, family caregiving arises within a long-standing, often life-long, relationship. As a result, the caregiving relationship can be seen as an extension of the prior relationship history and its associated pattern of interactions. Second, informal caregiving is best understood when considered as a system, rather than as the characteristics of a single individual or a single relationship. As suggested by the stress-process model outlined above, events within the caregiver–care recipient relationship can have consequences, both positive and negative, for other familial relationships and caregiver well-being.

Despite the vast literature on family caregiving, surprisingly little is known about its effects on family relationships. In this section, the effects of caregiving on the relationship between caregiver and care recipient are considered, as well as the effects of caregiving on relationships outside the primary caregiving dyad, particularly between the caregiver and his or her spouse and siblings. Most is known about caregivers who are the spouses or children of the care recipient. Siblings sometimes take care of a brother or sister, and other relatives and even nonkin may take on the caregiving role (e.g., Cicirelli, 1985, 1992), but little is known about how caregiving affects these relationships.

7.22.9 NORMATIVE FAMILY RELATIONSHIPS IN LATER LIFE

Recognition of the importance of family relationships in later life has spawned a large body of research examining normative patterns of intergenerational exchanges. Overwhelmingly, this literature has demonstrated that older adults typically remain both active donors and recipients of support until very late in life. In this intergenerational context, older adults generally give more to their adult offspring than they, in turn, receive (Eggebeen & Wilhelm, 1995; Zarit & Eggebeen, 1995).

Reciprocity and the balance of exchanges have received particular attention because of their potential influence on psychological well-being (e.g., Ingersoll-Dayton & Antonucci, 1988). Using a large, nationally representative Canadian sample, Hirdes and Strain (1995) found a curvilinear relationship between age and the balance of instrumental exchanges between generations with the greatest balance occurring at midlife. Morgan, Schuster, and Butler (1991) examined the balance of exchange between older parents and their adult offspring as a function of parents' age. They found that parental giving and receiving declined with increasing parent age, but that older adults typically continued to give more than they received beyond age 85. Unlike Hirdes and Strain (1995), who focused only on instrumental exchanges, Morgan et al. (1991) also considered emotional support, which partially accounts for these observed differences.

Related to intergenerational exchanges are norms of filial responsibility. Hamon and Blieszner (1990) report that older parents and their children strongly endorse expectations of filial responsibility in times of need. There is ample evidence that these norms are robust across a wide variety of cultures and family structures (e.g., Brody, Johnsen, & Fulcomer, 1984; Chow, 1983; Fadel-Girgis, 1983; Hanson, Sauer, & Seelbach, 1983; Kendig & Rowland, 1983; Kivett & Atkinson, 1984; Maeda, 1983; Weihl, 1983; Worach-Kardas, 1983).

It appears that these cultural norms are readily translated into action, with relationships with adult children assuming greater importance for older adults in later life. Field and Minkler (1988) report that frequency of contact with adult children remains high from early to late old age. Whereas interactions with friends and their perceived importance decreases, satisfaction with relationships with children increases across the same period.

7.22.9.1 Family Structure and Caregiving

Caregiving grows out of these normative patterns of intergenerational exchange and interaction. Strong social norms govern who is most likely to become a caregiver. By any estimation, gender is the single strongest predictor of who will become a caregiver, with women comprising approximately 70% of all caregivers (Aneshensel et al., 1995; Stone, Cafferata, & Sangl, 1987). Most research has suggested that caregivers assume their role hierarchically within the family structure. Married individuals will turn first to a spouse for assistance in times of need. In the absence of a spouse, adult children are the next choice, followed by siblings, more distant relatives, and finally neighbors and friends (e.g., Penning, 1990). Wives, daughters, and daughters-in-law are the most common female caregivers, and husbands the most common male caregivers, followed distantly by sons (Aneshensel et al., 1995; Stone et al., 1987), who are only likely to assume the caregiving role in the absence of a female sibling (Horowitz, 1985).

In most caregiving situations, one person takes over the primary responsibility, providing the most help or spending the most time with the care recipient. Other family members may also provide considerable assistance. Although sons do not frequently assume the role of primary caregiver, they often give considerable help to their sisters. Similarly, a parent caring for his or her spouse will typically receive help from children. The relationships between primary and secondary caregivers are an important source of support, but can also be a focal point for conflict and disagreement (Semple, 1992).

In studies of how siblings take responsibility for care tasks, Matthews (1987; Matthews & Rosner, 1988) found that family structure (birth order, number of siblings, gender composition), history of parent-child affectional ties, and extrafamilial roles (employment status, marital status, and geographic proximity) all influence which sibling provides parent care (see also Brody, 1990). In families with two or more adult daughters, shared care was the norm, whereas sons consistently appeared to play less central roles.

According to Matthews (1995), both adult daughters and sons draw upon cultural norms for gender-appropriate behavior in shaping their caregiving behavior. Adult daughters are viewed as being primarily responsible for caregiving activities regardless of the actual division of labor, and their brothers' contributions to caregiving are seen as peripheral and unimportant.

Another important distinction in the caregiving situation is whether or not the caregiver and care recipient share the same household (Chappell, 1990; Tennstedt, Crawford, & McKinley, 1993; Townsend, Noelker, Deimling, & Bass, 1989). Spouse caregivers usually live in the same household, but children may or may not live with a parent. An important source of cross-cultural differences is the extent to which aged parents and their adult children share a household (Sundström, 1992; Davey et al., 1996). In some countries such as the USA, rates of shared households have been relatively high, with children frequently taking in a disabled parent. In other countries, such as Sweden, two-generation households have been quite rare.

The implications of shared or separate households are considerable. A shared household probably places more continuous strain on family members and has been found to result in higher levels of stress (Townsend et al., 1989). In contrast, some different problems confront families who provide care to a parent in a different household, including needing to coordinate help that may be brought into the home, and worrying about the safety of the elder when no one is around. A special situation is trying to provide care at a long distance, which can be a source of considerable anxiety to children.

Marital status of parents and their children have emerged as important predictors of caregiving and intergenerational exchange. Specifically, parental divorce has been shown to affect the quality of relationships and frequency of contact between fathers and their adult children and the frequency of contact with mothers (Webster & Herzog, 1995). In general, the effects of divorce were much greater for fathers than for mothers (Cooney & Uhlenberg, 1990; White, 1992).

Disruption in adult children's marital status has also been found to relate to lower levels of help given to elderly parents, perceptions that parents need less assistance, and a lower sense of filial obligation to provide assistance (Cicirelli, 1983). A study by Brody and her colleagues (Brody, Litvin, Albert, & Hoffman, 1994) elaborates upon these findings, suggesting that daughters' marital status can have considerable effects on the amount of care they provide to an older parent. In particular, never-married and widowed daughters were found to provide the greatest proportion of care needed by a frail older parent by themselves. Never-married daughters, in particular, were most likely to be sole caregivers for their elderly parents. Conversely, married daughters were more likely to receive assistance with care tasks from informal sources, and divorced daughters were more likely to report using formal services.

7.22.9.2 Caregiver–Care Recipient Relationships

The relationship between caregiver and care recipient is an important and often overlooked aspect of these situations. Probably the most important distinction is between cognitively-intact people who can maintain some continuity in their relationships with caregivers, and those suffering from dementia.

Providing care to an elderly relative with dementia presents stressors which differ in fundamentally important ways from situations in which cognition is spared, or recovery is possible. When comparing caregivers of people with dementia but no physical limitations to caregivers of people with functional disabilities but no cognitive deficits, Birkel (1987) found that the former experienced much higher levels of care-related stress. In a comparison of caregivers of relatives with dementia and of relatives with cancer, Clipp and George (1993) found that dementia caregivers reported poorer self-rated health, greater substance use, poorer emotional health, reduced social functioning, and poorer financial status, even when the effects of employment status, age, and duration of illness were controlled.

Wright (1993) compared a small, nonrepresentative sample of Alzheimer's disease (AD) caregiving couples with well couples across a variety of dimensions. The study is unique in that she considered the perspective of both members having each report on specific aspects of their marriage. AD caregivers reported decreased companionship and difficulty dealing with changes in sexual intimacy. Wright also found that ratings of past marital happiness were associated with current valuing of the afflicted spouse as a unique individual, but not with future commitment, which was lower among caregiving spouses.

Majerovitz (1995) found a relationship between family adaptability and outcomes for caregivers of dementia patients. Caregivers who reported high adaptability in their families had lower depression, even when there were high levels of care-related stressors. She also reported that low-adaptability spouses were more likely to cling to an unrealistic role for their cognitively-impaired spouse, expecting their partner to continue to meet former expectations. While these data are cross-sectional, they suggest that caregivers with more realistic expectations of their demented spouse are likely to experience fewer negative consequences as a result of the care they provide.

In spousal relationships, relationship quality between the caregiver and care recipient may also play a role in the decision to institutionalize. Pruchno, Michaels, and Potashnik (1990b) found that spouses reporting a better quality of relationship with the care recipient reported less desire to institutionalize, but this finding did not extend to actual decisions regarding institutionalization. By the same token, however, desire to institutionalize was a strong predictor of actual institutionalization, suggesting that an indirect link may exist.

These findings offer support to the idea that there is something uniquely debilitating about losing a spouse to dementia as compared to another terminal illness in which cognitive functioning is typically spared. Because dementing illness results in deterioration in cognition and behavior, patients lose the ability to participate in the family or to have a say about the course of their own care. Caregiving becomes completely one-sided, with the patient unable to reciprocate in any way and, often, unable even to acknowledge the help that is provided. The progressive course of these disorders means that families face a somewhat predictable pattern of deterioration. Care of patients who are cognitively intact is not without its stresses; rather, care demands do not have the unrelenting pattern found in dementia and care recipients can acknowledge and show appreciation for the assistance they receive. Families caring for someone with another type of major psychiatric disorder may experience similar levels of distress as caregivers of dementia patients (Pearson, Verma, & Nellett, 1988). It may be that disorders which involve behavioral and emotional disturbances, and which are more disruptive of the usual family relationships, have the greatest impact on caregivers. The past relationship between children and their parents has considerable influence on caregiving experiences. Feelings of attachment and obligation have both been found to predict the amount of help daughters provided to their older parents (Cicirelli, 1993). Those who reported stronger feelings of attachment experienced lower levels of burden, whereas those who reported higher levels of obligation experienced higher levels of burden. Thus, children providing care out of a sense of obligation rather than affection may experience greater negative consequences as a result.

There are other important implications of the quality of prior relationships for the caregiving experience. Caregivers with a poor relationship with the care recipient are less likely to assume the caregiving role and, if they do, to experience more stress within it (Whitlatch & Noelker, in press). In an intriguing study by Uchino, Kiecolt-Glaser, and Cacioppo (1994), higher ratings of pre-illness affection for the care recipient were associated with lower heart rate reactivity, a physiological indicator of stress, measured two years later.

Walker, Martin, and Jones (1992) examined the role of intimacy in predicting adult daughters' and mothers' perceived costs and benefits of caregiving. Adult daughters' feelings of intimacy were associated with fewer feelings of having insufficient time for extra-caregiving activities, less frustration with caregiving, and less anxiety about providing care. For mothers receiving care, intimacy was related to less anger and resentment about the care they received. Other research has found conflict in the caregiver–care recipient relationship to be associated with greater caregiver strain and negative affect (Sheehan & Nuttall, 1988).

Townsend and Franks (1995) found that adult childrens' perceptions of relationship quality with their parent was an important mediator between the parent's cognitive impairment and the adult child's well-being. In their study of 90 adult–child caregivers, perceived closeness was associated with lower levels of reported caregiver burden and a greater sense of caregiving efficacy. Their study also underscores the importance of conflict in the relationship, which was associated with higher levels of stress, efficacy, and depression.

While most research has examined quality of the relationship, Aneshensel and her colleagues (1995) looked at the extent to which caregivers reported the loss of their relationship with a relative suffering from dementia. As their relative's disease progressed, caregivers reported a greater loss of the relationship. This sense of loss continued to play a role even after the patient's death. Caregivers who had previously reported a greater loss recovered more quickly than those who still held onto the relationship.

One extreme outcome of a poor relationship between caregiver and care recipient is violence directed toward the elderly care recipient. In a study of 236 caregivers to a relative with dementia, Pillemer and Suitor (1992) examined predictors of violence and violent feelings toward the care recipient. With regard to care recipient characteristics, they found that both violent behaviors and disruptive behaviors were associated with caregivers' greater fear of becoming violent with their relative. Violent behaviors by the care recipient were also associated with a greater likelihood of actual violence on the part of the caregiver. Caregivers who lived with their relative were more likely to report being afraid of acting violently toward their relative, and spouse caregivers were more likely to have acted violently toward their relative than adult children.

Thus, there is evidence to suggest that aspects of the past and present relationship quality between caregivers and care recipients play an important role in the caregiving experience, and that these characteristics have an effect, for both spouses and adult children, on the burden experienced as a result of caring.

7.22.9.3 Social Support from Family and Other Informal Sources

One of the most important sources of help to caregivers is the assistance and emotional support provided by other family members. Although actual estimates vary widely, there is general consensus that a majority of caregivers have support in their role from a secondary caregiver (e.g., Aneshensel et al., 1995; Stone et al., 1987; Tennstedt, McKinlay, & Sullivan, 1989). Social relationships can also involve conflict, and it has been suggested that negative social interactions can have greater impact on satisfaction with social support than measures of support received from others (e.g., Krause, 1995). In many instances, the same relationship can be a source of support and conflict.

Clipp and George (1990a) report considerable stability in the social support caregivers receive over a one-year period. They also report a lack of relationship between objective needs (dementia symptoms, duration of caregiving) and social support received. In other words, some families provide support whether the need for help is great or small, while other families do not help much at all, whatever the circumstances.

Thompson and colleagues (Thompson, Futterman, Gallagher-Thompson, & Lovett, 1993) examined potential differential effects of various types of social support in predicting measures of caregiver burden. Reduced social participation with friends and family was the most consistent social support predictor of the burden indicators they considered (see also, Haley et al., 1995). Specifically, higher levels of social participation were associated with lower levels of burden, having a less restricted social life, and a less negative relationship with the care recipient. That social support may also come with associated costs to caregivers was also indicated by their research. Caregivers who received material aid or financial assistance tended to report more negative interactions with family and friends.

Using longitudinal data, Aneshensel and her colleagues (1995) expanded on this theme that different types of support are related to different outcomes. Using the stress process model described earlier, they found that instrumental support from informal helpers (family and friends) can contain the experience of overload that results from primary stressors, whereas emotional support is not effective to this end. Similarly, instrumental support reduces proliferation of stress into other important roles held by the caregiver, such as work. Emotional support appears to be most effective in containing the effects of stress on outcomes such as depression.

For caregivers who are married, their relationship with a husband or wife can be both a source of support or a point of increased strain, as they experience conflicting demands on their time and energy. In an intriguing study, Creasey and his colleagues (Creasey, Meyers, Epperson, & Taylor, 1990) investigated how caring for a parent or parent-in-law with AD affected the relationship between husband and wife with each other and with their parents and children. Women caring for a parent (or parent-in-law) experienced a loss of support both from their husband and parent. Support from their own children, however, was not affected by caregiving, nor did their involvement lead to increases in negative interactions with their spouse or parent. Their husbands reported less support from parents, but not from wives or children.

Suitor and Pillemer (1992; see also Franks & Stephens, 1996) found, not surprisingly, that when husbands provided emotional support to caregiving wives, marital satisfaction was higher. Conversely, marital satisfaction was lower when husbands hindered their wives' caregiving in some way.

Caregiving grows out of a relationship with a long history and previously well-established expectations for interactions. There is evidence that this history has a substantial influence on the caregiving experience. As the nature of the caregiver–care recipient relationship changes, positive and negative interactions in other important family relationships can also be found. How much the support from others helps caregivers depends on how and what type of support are given, in a complex, but comprehensible fashion. Support from family and friends is a readily available resource for caregivers, which is not limited to the working hours of formal service agencies, nor bound by bureaucratic rules. Finding ways to increase support to caregivers while reducing conflict is an important goal for clinical intervention, as we shall discuss later.

7.22.10 SECONDARY STRESSORS: COMPETING ROLES AND STRESS PROLIFERATION

Caregivers have dimensions in their lives outside the demands of caregiving. These other roles can create additional stress on the caregiver, or they can help to alleviate the stress of caregiving, depending on the nature and quality of these outside roles. In the model guiding this chapter, these outside influences fall under the term secondary stressors.

Secondary stressors contain both role strains and intrapsychic strains. Role strains may arise from family, work or informal responsibilities outside of the caregiving situation, but are generated or aggravated by the demands of caregiving (Aneshensel, Pearlin, & Schuler, 1993). These stressors include family conflict, work-caregiving conflict, and economic strain. Intrapsychic strains involve dimensions of self-concept and psychological states.

There are two main hypotheses regarding the effect of different roles on the well-being of a person. The scarcity hypothesis proposes that additional roles create strain. Goode (1960) introduced the concept of role strain, or the difficulty in meeting expected role demands. In this view, role strain is seen as normal and even inevitable; therefore, the task for everyone is to discover ways to reduce this strain. This corresponds to the competing commitment perspective within the caregiving literature. This concept focuses on the time dimension of the conflicts among multiple roles, and assumes that the other roles of caregivers create further demands on the caregivers' time (Stoller & Pugliesi, 1989).

In contrast to the scarcity hypothesis, Sieber (1974) introduced the expansion hypothesis, that there are positive effects of accumulating additional roles. Even though the obligations of a role may be taxing, the rights gained within that role may negate any detrimental outcomes that might occur because of the acquisition of the role. One way in which multiple roles might compensate for role strain is by allowing people to fall back on successes in one role if they fail within another. A number of studies have found that occupying multiple roles is associated with better overall well-being (Thoits, 1983; Verbrugge, 1983).

One important focus of multiple roles is on daughters who balance caregiving with being a wife and mother. Studies by Stephens and her colleagues (Stephens, Franks, & Townsend, 1994; Stephens & Franks, 1995) have identified both positive and negative consequences of these multiple roles. An important feature of these studies is that they examine how each role has stresses and rewards, which affect how one role might affect the other. Both stress and rewards in the role of mother were associated, respectively, with positive and negative affect reported by caregivers. Stress and rewards in the role of wife were also associated with ratings of physical health.

Quality of the marital relationship can also have important consequences for the effects of caregiving on adult daughters, and vice versa. Stephens and Franks (1995) examined positive and negative perceptions that one role (either caregiving or spousal) had affected the other ("spillover"). Whereas positive spillover from the role of wife to caregiver was only related to higher levels of marital satisfaction, positive spillover from the caregiver to wife role was associated with lower levels of depression and greater positive affect. Conversely, negative spillover from wife to caregiver roles was associated with less positive affect and lower marital satisfaction; negative spillover from caregiver to wife roles was associated with significantly greater depression.

The main area in which these competing hypotheses about multiple roles have been explored is work and caregiving. Work has a central role in many people's lives and the difficulties that balancing work and caregiving responsibilities pose make it a particularly challenging issue. The rapid increase in the number of working women in first-world nations has made work and caregiving conflict an important social issue, as well as a consideration in clinical situations. An unusual longitudinal study of work and caregiving documents the increased rate at which women are combining both roles. This study examined a group of women who were originally interviewed in 1956 and then interviewed again 30 years later about caregiving histories (Moen, Robison, & Fields, 1994). Over 60% of the women in the study were caregivers to relatives with disabilities at some time in their lives. In this study, women were as likely to combine working and caregiving as they were to be only caregivers. Women seem to be adding to their roles rather than giving up a role when a new role must be acquired.

Working and caring for an elderly relative produces some special challenges and issues. When studying mothers and their daughter caregivers, Brody and Schoonover (1986) found that mothers received the same amount of help whether their daughters worked or not. But when employed women were compared with their nonemployed sisters, significant differences were found in the amount of help given when their parents' functional status was poor, with working women providing less assistance (Matthews, Werkner, & Delaney, 1989). Working women, then, are often providing extensive help in the caregiving role, but there are limits to their ability to help, which become evident in situations involving more extensive disabilities.

The question of whether an employed woman should make adjustments to her employment situation or quit her job is one that many caregivers face. A sizable number of caregivers leave their jobs within three months of becoming a caregiver (Franklin, Ames, & King, 1994). Leaving a job or reducing work hours is the most dramatic change that a caregiver can make in order to deal with the competing demands of work and caregiving. Workers generally try to rearrange their schedules or reduce their hours before leaving the job (Mutschler, 1994). There are many different factors that contribute to the decision or need to leave a job because of caregiving responsibilities. Caregivers who leave their jobs or reduce their work hours tend to have relatives who have more severe disabilities (Brody, Kleban, Johnsen, Hoffman, & Schoonover, 1987) and have faced work constraints for a longer period of time (Mutschler, 1994).

Reports of strain are common among working caregivers (Mutschler, 1994; Scharlach & Boyd, 1989). But there is the question of what contributes to that strain. The four main predictors of conflict between work and caregiving are: (i) the elderly family member's emotional health; (ii) the number of caregiving tasks performed by the caregiver; (iii) the presence of children in the caregiver's residence; and (iv) having caregiving responsibilities when beginning at the current job (Gibeau & Anastas, 1989). In addition, sociodemographic variables such as the employee's gender, marital status, household income, job status, occupation, and flexibility of work schedule are related to employees' levels of absenteeism and stress (Neal, Chapman, Ingersoll-Dayton, Emlen, & Boise, 1990). Other studies have found that the severity of disability of the elderly relative and the intensity of the caregiving responsibilities are related to work and caregiving conflict (Gibeau & Anastas, 1989).

Beyond the simple distinction between working and nonworking caregivers, the type of occupation has an effect on strain or burden. Mutschler (1994), for example, reports that production workers have less opportunity to adjust their work and care demands than workers in executive, sales, or clerical positions.

The relationship between experiences in the employment role and caregiving stress may be more complicated than originally thought. As was the case when balancing roles of caregiver, mother, and wife, the dual commitments of work and caregiving involve rewards as well as stress. High satisfaction with work seems to be associated with fewer depressive symptoms, except for those caregivers who experience high levels of caregiving stress (Martire, Stephens, & Atienza, 1997). The number of hours that a caregiver worked is associated with negative outcomes under conditions of high caregiver stress. Martire, et al. (1997) also found that women working part-time experienced poorer physical health and less positive affect than those women who were working full-time. One reason for this may be the increased amount of time that full-time workers are away from the impaired relative (Brody, 1990; Scharlach, 1994). Another reason may be that full-time work provides greater knowledge, benefits, and support (Matthews et al., 1989).

Workers tend to be interested in work benefits that are designed to make work and caregiving easier. The ideas for benefits that generated the most interest were respite care, flexible work hours, reduced hours without reduced benefits, adult day care, and job sharing. Caregivers using formal services understood that the availability of those services was critical if they were to maintain their employment and meet their family member's need for care (Gibeau & Anastas, 1989).

In summary, the findings from research on competing roles indicate that the additional roles that a caregiver occupies can result in both stress proliferation and containment. In order to get a complete understanding of the challenges that the caregiver faces, it is necessary to understand the quality of the roles and the rewards as well as stresses that the various responsibilities bring. Advising a caregiver, for example, to reduce her work responsibilities before having a clear picture of the entire caregiving situation would be ill advised. Rather, the challenge in clinical situations can be to find ways to balance competing roles more effectively and to minimize the spillover of stress from one activity to another.

7.22.11 OUTCOMES OF CAREGIVING: HEALTH AND MENTAL HEALTH EFFECTS

Caregiving is a uniquely stressful event. Being a long-term caregiver has been found to be associated with a variety of negative outcomes. The consensus among studies examining physical and mental health outcomes is that a majority of caregivers report feeling physically and emotionally distressed (Anthony-Bergstone, Zarit, & Gatz, 1988; Brodaty & Hadzi-Pavlovic, 1990; Clipp & George, 1990b; George & Gwyther, 1986; Haley, Levine, Brown, Berry, & Hughes, 1987; Kinney & Stephens, 1989). Several studies report higher levels of psychological morbidity among caregivers compared to noncaregiving samples of the population. Anthony-Bergstone and her colleagues (1988) noted the increased feelings of hostility, anger, and anxiety among caregivers as compared to the general population. An Australian study showed that mean scores on the General Health Questionnaire (GHQ), a measure of psychological morbidity, were higher in the caregiving sample and among caregiving spouses than the general population or other subsamples of caregivers (Brodaty & Hadzi-Pavolovic, 1990). Women caregivers generally report higher levels of psychological distress than men (Anthony-Bergstone et al., 1988; Zarit & Whitlatch, 1992).

Schulz, Visintainer, and Williamson (1990) reviewed several studies showing the psychiatric morbidity effects of caregiving. In studies using self-report measures such as the Beck Depression Inventory (BDI) or the Center for Epidemiological Studies Depression Scale (CES-D), three general conclusions emerged. First, greater severity of the care recipient's problems is linked to more depressive symptomatology. Second, women have higher rates of depression than men. Third, the more representative the caregiving population, the lower the rate of depression. Thus, caregivers drawn from specific subsamples such as daughters taking care of severely demented relatives or those seeking help from a service program show higher rates of depression symptoms.

A second group of studies has used clinical assessment tools (e.g., the Schedule for Affective Disorders and Schizophrenia Interview) which yield rates of clinical diagnoses of depression and other problems. These studies have found that caregivers frequently meet diagnostic criteria for depression or other diagnoses (e.g., Cohen & Eisdorfer, 1988; Drinka, Smith, & Drinka, 1987; Goldman & Luchins, 1984). In one of the most comprehensive studies of this kind, Gallagher and colleagues (Gallagher, Rose, Rivera, Lovett, & Thompson, 1989) found prevalence rates for depression ranging from 31% for men to 46% for women. These studies provide strong evidence that caregivers are at risk of increased psychiatric symptoms and clinical disorders.

The model of the stress process described earlier in the chapter illustrates how primary and secondary stressors can have a cumulative effect on caregiver mental well-being and physical health. Among the primary stressors, behavior problems are most likely to lead to adverse outcomes for family caregivers. The common behavior problems identified by caregivers as difficult or stressful for them are incontinence of the bowel and/or bladder, crying easily, hiding things, acting restlessly or agitated, and becoming irritable, angry, or accusatory (Haley & Pardo, 1989). These behavioral problems require vigilance, surveillance, and control on the part of the caregiver. Pruchno and Resch (1989) found that asocial and disoriented behaviors on the part of the care recipient are associated with greater burden, decreased social participation, and less satisfaction with caregiving. For forgetful behaviors, the consequences for caregiver's mental health increase at first, and then diminish as the severity of behavior problems increases, suggesting a curvilinear relationship between the two.

In a study of depression in dementia caregivers, Redinbaugh, MacCallum, and Kiecolt-Glaser (1995) found that caregivers who experienced chronic depression over a three-year period reported their relative's behavior as more problematic, and had higher levels of upsetting social support than non-depressed caregivers or caregivers who had experienced a transient depressive episode during the course of the study.

Vitaliano and colleagues (Vitaliano, Young, Russo, Romano, & Magana-Amato, 1993) were interested in examining the possibility that caregiver behaviors, specifically in the form of expressed emotion, were predictive of subsequent care recipient behaviors one and a half years later. Controlling for initial levels of problem behaviors, dementia patients who were cared for by an individual with high levels of expressed emotion displayed significantly more negative behaviors at follow-up. These findings are significant because caregiver expressed emotion is correlated with higher levels of depression, suppressed anger, and lower life satisfaction (Bledin, MacCarthy, Kiupers, & Woods, 1990; Vitaliano et al., 1993).

Burden, guilt, inadequacy, and negative perceptions of patient mood and functioning are words that describe the motivation to engage in caregiving activity (Hadjistavropoulos, Taylor, Tuokko, & Beattie, 1994). Lack of time, lack of help, and difficulty in managing patient behavior describe the caregiver's ability to engage in the caregiving process. These stressors have a cumulative impact on caregiver well-being.

Two broad domains have been investigated for the extent to which they buffer or contain the stressors of caregiving: social support and coping. The role of social support was reviewed earlier. Coping resources potentially represent an important way of containing stress. Research in this area has identified some promising leads on what type of coping strategies are more effective, but limitations in current research make it difficult to draw firm conclusions.

Pruchno and Kleban (1993) studied the relative effectiveness of emotion-focused vs. problem-focused coping strategies in mediating stress experienced by caregivers to an institutionalized relative. Their findings suggest that, contrary to coping research in other caregiving contexts (e.g., Stephens, Norris, Kinney, Ritchie, & Grots, 1988), emotion-focused coping was associated with better mental health than problem-focused coping. These findings highlight the importance of recognizing caregiving as a chronic stressor which is less amenable to change than many other situations. As a result, caregivers may be more successful if they focus on dealing with their responses to the situation than if they take a more traditional, instrumental approach.

Williamson and Schulz (1993) examined the relationship between a number of coping strategies and the burden experienced across three domains of the caregiving relationship: dealing with memory deficits, loss of communication, and the decline of a loved one. Their results suggest that different strategies are more and less successful, depending on the specific domain. Use of wishfulness as a coping strategy was related consistently to the experience of greater burden for all three stressors considered. Similarly, use of direct action strategies in response to memory deficits was associated with greater depression. Strategies which are more successful for caregivers included using relaxation as a way of coping with memory problems and seeking support to deal with loss of the relationship with the care recipient. Finally, acceptance of the situation was associated with lower depression related to loss of a loved one and loss of communication.

Gignac and Gottlieb (1996) considered caregivers' use of 12 kinds of coping strategies in dealing with specific behavior problems exhibited by the care recipient. They found considerable variation in the kinds of strategies caregivers used over a five-month period, suggesting that caregivers modify their approach to dealing with stressors over time. Caregivers who focused on gaining insights into how their coping strategies affected the relationship with the care recipient, both in attributing behavior problems to the disease process and in understanding the contingencies between caregiver and care recipient behaviors reported lower levels of stress at follow-up, even when initial levels of stress were controlled.

Thus, the effects of coping are complex. Strategies which attempt to change elements of the disease process are unsuccessful and perhaps even harmful. Conversely, strategies which focus on acceptance of changes in the caregiver–care recipient relationship appear much more helpful. Again, support seeking can be helpful in this regard.

One of the most comprehensive examinations of the determinants of mental health problems of caregivers was conducted by Aneshensel et al. (1995). Using a longitudinal panel of caregivers of dementia patients, they were able to examine how changes in stressors were related to increased or decreased mental health symptoms over a four-year period of time. Stress proliferation took place when primary stressors, such as behavior problems or ADL disabilities, led to feelings of overload or role captivity (see above). Thus, there needed to be both the occurrence of specific care-related problems and a subjective sense that those problems were overwhelming. In those instances, secondary stressors such as work or family conflict were more likely to emerge, as were mental health problems. In turn, receiving more informal social support from family and better coping, specifically higher feelings of mastery, resulted in some containment of stress. These results suggest that both objective indicators of the patient's disabilities and caregivers' subjective evaluation of their impact are needed to understand the processes leading to depression and other mental health problems.

Reports that caregiving is associated with high rates of psychiatric symptoms are probably not surprising, given the multiple pressures experienced. More intriguing are the results of studies which suggest that caregivers may be at risk of poorer health or even increased risk of mortality. There is less consistency across studies in reporting health effects, but sufficient evidence has been found to suggest there is at least some risk.

Studies of the effects of caregiving on health generally focus on self-reported problems, although a few investigations have used more objective indicators. Caregivers generally report they are in poorer health than age-matched controls (e.g., Pruchno & Potashnik, 1989; Schulz et al., 1990). In a nationally-representative sample from the USA, one-third of women caregivers reported fair or poor health compared to only one-fifth of age-matched peers (Stone et al., 1987). Other studies (e.g., Haley et al., 1987; Pruchno & Potashnik, 1989) have found that caregivers visit their physicians more often and use more prescription drugs compared to noncaregivers. These results, however, have not been confirmed in other studies of medical service use (e.g., George & Gwyther, 1986; Kiecolt-Glaser et al., 1987). Finally, several studies have found specific increases in health problems, such as respiratory illnesses, hypertension, and cardiovascular disease (Moritz, Kasl, & Ostfeld, 1992; Schulz et al., 1990; Wright et al., 1993).

Undoubtedly, the response of caregivers to chronic caregiving stress can follow the patterns of the general adaptation syndrome (Selye, 1976). Caregivers are exposed to a great deal of rage, grief, despair, and other intense emotions that can have effects on the blood and heart as well as clinical depression and anxiety. Caregivers may also exert a great deal of physical effort that can raise blood pressure and initiate atherosclerotic responses. The most common risk factors for health problems include being a spouse caregiver (Wright et al., 1993), living arrangements (Pratt, Wright, & Schmall, 1987), financial strain, and the intensity of primary stressors and secondary stressors. As stated before, these risk factors become detrimental to health when they are chronic.

One of the most intriguing findings linking chronic stress to health problems is that caregivers of dementia patients may experience changes in immune system functioning. In investigations which examined caregivers and a sample of matched controls, Kiecolt-Glaser and her colleagues (Keicolt-Glaser et al., 1987; Kiecolt-Glaser, Dura, Speicher, Trask, & Glaser, 1991) found that caregivers had poorer immune function, and these changes were linked to higher rates of illness in some subjects.

Caregivers' health problems may increase due to compromised self-care and health behavior (Brodaty & Hadzi-Pavlovic, 1990; Kwee, Zarit, Edwards, Davey, & Jarrott, 1995; Lieberman & Fisher, 1995). Caregivers may not go to the doctor when ill, or may not get enough rest or exercise. Nutritional intake can be affected, with some caregivers not getting adequate nutrition and others eating too much. Other caregivers may smoke more, use alcohol excessively, or even take tranquilizing medications prescribed for the patient. Consistent with the stress process model, compromised health behavior follows a model of competing demand whereby caregivers are faced with dwindling resources of energy, time, and money, and so must choose between self-care and care of their relative (Kwee et al., 1995). Often, caregivers feel no choice but to neglect their own health to continue to give care to their loved one (Bunting, 1989). Neglected self-care then acts as a mediating variable between stressors and the outcome of physical and mental health.

The process by which mental and physical health are affected as a result of caregiving stressors is admittedly complex. Uncertainties in causal directionality of independent and dependent variables and the possible existence of feedback loops due to the dynamic nature of an elder's disabilities add to the difficulty of making causal statements. Based on findings of the research, a theoretical model can be summarized as follows: the relative's illness creates the environment of primary stressors that proliferate or spillover to the creation of secondary stressors. Primary stressors, as represented by the mental and physical hardships of caregiving (e.g., motivation and ability), have both a main effect and a mediated effect (through secondary stressors) on caregiver mental and physical health. The secondary stressors that result are manifested through the caregiver's inability to take proper physical and mental care of him/herself because of a lack of energy or time. Prolonged exposure to primary and secondary stressors affects well-being. Research suggests a lagged relationship between depression and physical health, with depression leading to greater levels of physical illness (Pruchno, Kleban, Michaels, & Dempsey, 1990a).

In this framework, healthfulness is the result of continually achieving the best possible adaptation to the environment and involves interdependent physical, psychological, and social aspects (Capra, 1982). Illness occurs if stress pushes the system away from balance in response to environmental influences. To regain balance, the individual depends on his/her physical and mental response mechanisms. Because of the extensive demands that caregiving places on primary caregivers, it is not surprising that some fail to adapt to changing environmental situations and so experience severe disruption and breakdown. The challenge now is twofold: to identify the factors that protect good health in caregivers, and to design interventions that alleviate chronic stress at points in time before the body becomes ill.

Although the negative outcomes of caregiving have been emphasized, these adverse effects are sometimes balanced by positive experience. Feelings of gain, a growing sense of competency, or satisfaction with having met one's obligations or done a job well can offset the negative consequences (Aneshensel et al., 1995; Lawton, Brody, & Saperstein, 1989a). For some caregivers, fulfilling an obligation in the ways they define it is more important than putting themselves at risk of health problems or depression. Clinicians need to recognize that these commitments represent deeply-held beliefs, and not neurotic guilt (although that can be a motivator for some people). Successful clinical interventions involve helping caregivers explore and sometimes redefine their commitments, rather than confrontation over what the clinical decides is inappropriate or irrational. Solutions may also involve finding better ways of fulfilling a commitment, as described in the following sections.

7.22.12 CLINICAL RESEARCH AND SERVICES

The unprecedented stress associated with family caregiving warrants an organized response to help share a portion of the burden. At the broadest level, it is in the interest of society to encourage families to provide care, since that reduces the demand for more expensive institutional care. From the care recipient's perspective, being cared for at home for as long as possible is usually preferred. Families as well usually prefer to do as much as they can to help older family members.

Clinical interventions can be organized with two goals in mind. Interventions can be used to bring in new resources in ways that directly relieve families of a portion of their responsibilities. Respite services such as adult day care or home help serve this function. The most extensive new resource is an institutional setting, which takes over most of the care. Interventions can also build up the caregiver's own abilities for managing the situation more effectively. The review that follows, will look first at respite services, including institutional care, and the benefits and drawbacks for families. It will then consider clinical interventions for caregivers.

7.22.13 RESPITE SERVICES

Respite services for caregivers of elderly relatives with dementia are widely advocated by professionals and sought after by caregivers. While there is no clear definition of what services comprise respite, day care, in-home help, and short- and long-term institutionalization are some of the most frequently used services. Respite is designed to serve both caregiver and patient. With the growing awareness that institutional care is often not optimal for older people, respite services have been promoted as a means by which impaired elders could remain in the community longer while reducing the cost of care provision.

Despite reports of high satisfaction with respite services (e.g., Burdz, Eaton, & Bond, 1988; Kosloski, Montgomery, & Borgotta 1990;

Lawton et al., 1989a, 1989b; Montgomery & Berkeley-Caines, 1989; Montgomery & Borgatta, 1985), there has not been much evidence of the benefits for caregivers or patients. Some investigations have found little impact of respite services, leading to the suggestion that these programs may be of no value to the family (Callahan, 1989). These negative findings, however, may be the consequence of poor programing or low or inconsistent levels of service utilization. This section describes different respite services and considers outcomes of and obstacles to utilization.

7.22.13.1 Adult Day Care

Adult day care programs are designed for individuals with dementia or other mental or physical disabilities. They provide the patient with a few hours of supervised, structured activity, and give the family caregiver time to rest or perform other chores and responsibilities. Typically an individual will attend a day care program two to three days each week for about five hours each day (Weissert et al., 1990). Program activities include orientation exercises, socializing, and reminiscing. Programs frequently provide services such as health screening, podiatrist and eye doctor visits, and prescription administration. Out-of-home care allows the caregiver to stay at home and enjoy their privacy or have time with other family members (Montgomery, 1995). Day care gives the patient the opportunity to meet others and have a change of scenery and activities while remaining in a safe environment.

Despite reports that caregivers are very satisfied with day care (Burdz et al., 1988; Lawton et al., 1989a, 1989b; Miller, Gulle, & McCue, 1986; Sands & Suzuki, 1983), benefits for the caregiver are equivocal. Some research supports the idea that day care usage results in improved physical and mental health, better relationships, and increased confidence in caregiving abilities among family caregivers (Montgomery & Borgatta, 1985; Scharlach & Frenzel, 1986). Other studies, however, have found that day care has little or no effect on caregiver burden or well-being (Burdz et al., 1988; Lawton et al., 1989b; Montgomery & Borgatta, 1989).

The effects, or lack thereof, of day care programs on caregiver burden may depend on the characteristics of the individual in the caregiving situation (Montgomery, 1995). Caregivers' employment, health, or responsibility for another family member could affect utilization and mediate the benefits of a day care program. Failure to find benefits may also be due to low utilization of programs. For example, Lawton et al. (1989a) found no effects of program participation on caregiver burden, but the caregivers in the program utilized day care less than once a month. Inability to control how much families utilize day care prevents firm conclusions being drawn about the benefits of adult day care. Some caregivers find the programs too inaccessible (MaloneBeach, Zarit, & Spore, 1992), and some relatives would rather remain at home.

Preliminary results from a large-scale trial of adult day care for dementia are more promising (Zarit, Stephens, Townsend, & Greene, 1996). In this study, caregivers received adequate amounts of respite (at least two days per week) from well-developed programs with expertise in care of dementia patients. Measures were also developed to be specific to the strains likely to be addressed by this kind of respite care. Results showed that caregivers using day care experienced lower feelings of overload, decreased anger and depression, and increased well-being compared to a control sample not receiving day care or other respite services. These results suggest that well-designed day care programs may relieve stress on caregivers.

7.22.13.2 In-Home Respite

Respite services provided in the home include attendance to the patient's physical needs, such as bathing and feeding, and "sitting" with the patient, either for a short period or overnight. Providers may include a companion, homemaker, home health aide, or a nurse (Isett, Kraus, & Malone, 1984). Levels of in-home care can be low or high, for a short or an extended period of time. Home respite is intended for patients who still live alone and need assistance, and for the coresiding caregiver of a more dependent patient.

Reports on benefits of in-home respite for the caregiver are generally positive. In-home care eliminates the need for transportation and may be scheduled with some flexibility (Montgomery, 1995). Benefits of in-home respite for the caregiver include improved mood (Gwyther, 1989) and decreased time spent in caregiving activities (Berry, Zarit, & Rabatin, 1991). In addition to being satisfied with in-home help, caregivers usually want more of it. At the conclusion of a 12-month program during which respite services were available, Lawton et al. (1989b) found that all caregivers in the study wanted more respite than any other class of services. MaloneBeach et al. (1992) also reported that caregivers wanted more help in the home.

Caregivers using in-home help have also voiced concerns with the services provided. Complaints about in-home help have focused on the qualifications, reliability, and continuity of respite providers, and availability and flexibility of scheduling (MaloneBeach et al., 1992; Montgomery, 1995). Obstacles to use of in-home respite include bureaucracy and disengagement of the caregiver from the service system (MaloneBeach et al.). Caregivers report that the structure of the service system is too narrow as it often does not meet all of the patient's or caregiver's needs. Caregivers also report that the system is unaccommodating of changes in patients' conditions unless they fit into the service levels of a schedule fixed by the respite program. These studies, which were conducted in the USA, may not capture caregivers' experiences in countries that provide better access to and coordination of services.

Although many consider in-home respite a means by which family caregivers may keep their relative with dementia in the community longer, use of respite is sometimes associated with short- or long-term institutionalization (Montgomery 1995; Montgomery & Borgatta, 1985; Montgomery & Kosloski, 1990). Lawton et al. (1989b) reported that caregivers who spent the most time and effort caregiving were most likely to use respite, particularly nursing home respite. As caregivers learn to be more comfortable sharing the burden of caregiving, it may become more acceptable to them to place their relative in an institution (Montgomery, 1995). An alternative explanation is that respite services are a stepping stone to institutionalization in the progression of the patient's illness.

7.22.13.3 Institutionalization and its Consequences

Short-term institutionalization offers overnight respite for family caregivers and provides skilled nursing for the patient. A short-term admission may be scheduled every couple of weeks for two to three nights or less frequently for one to two weeks (Montgomery, 1995). While short-term institutionalization offers the benefit of an extended period of respite, it tends to be less flexible than in-home care. Institutions cannot usually offer emergency respite because of the cost of keeping a bed free (Scharlach & Frenzel, 1986). Some patients have difficulty adjusting to a new environment (Mace & Rabins, 1981), and some will resist institutional respite for fear that it is a permanent placement (Montgomery, 1995). In a study of two weeks of institutional respite, Burdz et al. (1988) expected dementia patients to show increased problems due to the confusion of being in a new environment. The patients, however, demonstrated significant decreases in problem behaviors, and caregivers rated the program as highly beneficial, though few said their situation had improved after the program. Even with an extended break from caregiving, short-term institutionalization frequently precedes long-term placement (Montgomery & Borgatta, 1989).

Placement of a relative in a long-term care facility may be viewed as a final release of caregiver stress and responsibility, but it is accompanied by its own stressors (Townsend, 1990; Zarit & Whitlatch, 1992). Institutionalization may ease some of the strain of everyday care, but many caregivers continue to provide assistance even after transferring their relative to an institution. While primary stressors such as feelings of overload decrease following placement, feelings of depression and other mental health indicators are often unchanged (Zarit & Whitlatch, 1992). MaloneBeach et al. (1992) found that family caregivers with a relative in a nursing home reported that their relative still needed additional services not provided in the nursing home. Caregiving strains may persist for as long as four years after placement (Aneshensel et al., 1995).

The high levels of satisfaction which caregivers report with all respite services is encouraging. However, the results of empirical studies indicate that respite services do not reduce caregiver burden and stress consistently. A major problem in these studies has been low rates of use of services, which is often related to barriers to or problems in service delivery. Availability and accessibility is another obstacle to service utilization. For example, waiting lists at US day cares are more common than in Sweden where the municipality provides sufficient access to day programs (Jarrott, Zarit, Berg, & Johansson, 1996). Flexibility of scheduling and services are essential, along with personal contact with a case worker and regular care providers. Once caregivers are taken off a waiting list and admitted to a program, many patients attend sporadically because hours or transportation are inconvenient (Montgomery, 1995). Cost and clear guidelines on qualifications for different services need to be provided along with the support which permits all those in need of assistance to receive it.

Despite caregivers' concerns about respite programs and the inconsistent findings of benefits, families overwhelmingly say it is important to them and most would like more respite. Respite services may need to be considered for their long-term effects

(Fortinsky & Hathaway, 1990). Greene and Coleman (1990) suggest that available services may serve a preventive function, so that stress on the family does not reach an overwhelming level. Other families, however, consider caregiving a personal responsibility and only look for assistance when they have reached their own limits. More active recruitment of family members early in their caregiving career may result in greater long-term relief from burden and stress. Perhaps when caregivers feel more comfortable turning to respite services for assistance, utilization will be greater and effects will be evident.

7.22.14 CLINICAL SERVICES

Clinical protocols have been developed to lower stress on family caregivers by increasing their ability to manage care-related problems and improving their access to help from other family members and from formal services (e.g., Zarit, Orr, & Zarit, 1985; Zarit, 1996). These interventions build on existing research by identifying modifiable aspects of the stress process. As observed, behavior problems do not have a fixed or constant effect on caregiver outcomes. By improving how caregivers manage behavior disturbances, the impact of these problems will be reduced and caregivers will experience less stress. Similarly, increasing support from and reducing conflict with other family members should lead to improvements in the caregiver's situation.

A model for clinical interventions is shown in Figure 2. As with any intervention, the starting point is assessment. Assessment focuses on both care recipient and caregiver and serves several functions. First, it is important to confirm the care recipient's disabilities and to make sure that treatable components have not been overlooked. Symptoms of memory loss sometimes have treatable causes and should not be assumed to be due to dementia, unless an appropriate medical and neuropsychological examination has been conducted. Second, the clinician can assess the specific problems, disabilities, and strengths of the care recipient. Although the focus is often on decrements, care recipients may retain some abilities and resources, even when suffering from dementia or other progressive disorders. Strengths can include activities the person currently is able to perform, or past interests and activities that may be possible to enhance in the present situation. Third, the assessment should indicate which problems are stressful for the caregiver. As emphasized throughout this chapter, caregivers experience potential stressors in different ways. What is difficult for one person may not be so for another. That includes management of specific behaviors, such as incontinence or wandering, or handling potential conflicts between caregiving and work or other roles. Finally, the clinician should consider the extent to which the care recipient can participate in a clinical intervention, either jointly with the caregiver, or separately. There have been reports that short-term counseling and support groups are helpful for dementia patients in the earlier stages of their illness (Teri, 1994; Zarit & Zarit, in press). For cognitively intact people, a wide range of clinical interventions might be appropriate.

Following the initial assessment, clinicians can draw upon three treatment strategies when working with caregivers: increasing the caregiver's understanding of the patient's illness and disabilities; problem solving to manage daily care-related problems; and support. A starting point for interventions is often to increase caregiver's understanding of the care recipient's illness. Families often have questions that have not been answered by medical personnel, or they have trouble understanding the implications of a diagnosis. Often they will have questions about the possibilities for treatment.

An important facet of understanding the disorder is learning to view changes in the patient's behavior as part of the disease process. In disorders like dementia that have considerable impact on behavior, families often misunderstand or misinterpret common problems. They may, for example, believe that a patient asks the same question over and over to annoy the caregiver or to get attention, or because of laziness. Families should be encouraged to look at why someone with a memory-impairing disease would behave this way. They should also avoid reasoning or arguing with patients over factual issues. Patients may insist that they want to see their long-deceased mothers, or to go home, when they are already at home. Experience shows that caregivers cannot persuade patients they are mistaken. In fact, reminding patients that their mothers are dead is often upsetting, since they experience it as a new loss, and the result is more agitation. Instead, families are encouraged to think about why someone with memory loss would behave this way, and what they must be feeling at this time. Although families cannot respond effectively to the content of these types of communications, they can respond to the underlying emotions, for example, by providing comfort or reassurance, or by reminiscing about the patient's mother.

Increasing the caregiver's understanding of problem behaviors flows naturally into a more formal approach to problem solving. Problem

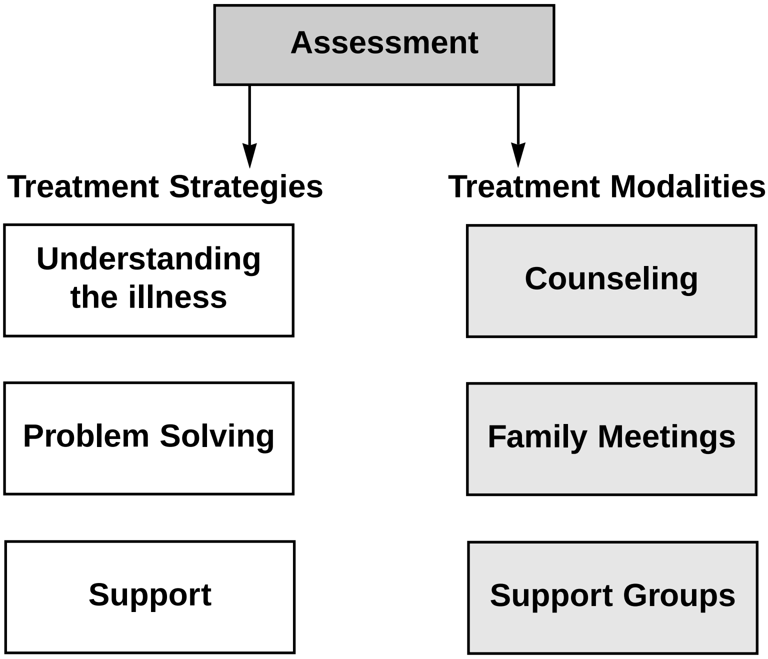


Figure 2 A model of intervention with caregivers.

solving can be used to address persistent troubling behaviors. Drawn from contemporary behavior therapy, problem solving involves a series of steps to identify causes and reinforcers of current problems and to generate and implement possible solutions (see Table 1). The starting point is to pinpoint a specific behavior or problem (e.g., agitation, depressed behaviors), and to have the caregiver observe it over a period of several days. Caregivers should note when the problem occurs, what went before it (antecedents), and what followed the behavior (reinforcers). This step provides a baseline of how often the problem occurs, against which interventions can be measured. It also identifies how the behavior may function. In dementia, for example, agitated behavior typically follows a period of inactivity or napping and is reinforced by attention.

Once a pattern is identified, the caregiver can be encouraged to think about strategies to change or head off the problem. Strategies need to be specific and practical and within the ability of the caregiver to manage. Caregivers may have difficulty selecting a solution. In that case, they can compare different strategies with the method of pros and cons, by which they write down advantages and drawbacks of each approach (including doing nothing). Planning and rehearsing the solutions before trying them out heads off problems if the plan is not realistic. After implementing a solution, caregivers should continue monitoring how often the problem occurs in order to evaluate how successful this strategy has been.

Although it is a behavior technique, problem solving is compatible with the use of medications. In fact, medications to control behavior or mood should be considered as one of the possible strategies for intervention. If the caregiver obtains a baseline of the frequency of the targeted problem before a medication is introduced, then it will be possible to get an accurate evaluation of the effectiveness of treatment. As clinicians know, medications often have uncertain and variable effects. Neuroleptics are widely used for control of behavior problems in the elderly, but they are not consistently effective or sometimes work for a while and then lose their effectiveness (Schneider, Pollock, & Lyness, 1990). By viewing medications as one of several possible

Table 1 The problem solving process.

	Stage
1	Pinpoint a behavior and assess when it occurs and how often
2	Identify antecedents and consequences
3	Identify possible strategies
4	Select a strategy (use pros and cons)
5	Plan and rehearse implementing the strategy
6	Try out strategy and evaluate

strategies and carefully monitoring their effectiveness, clinicians can develop more rational treatment approaches.

Problem solving can also be used to identify antecedents and consequences of caregiver stress. Rather than pinpointing a specific behavior problem, caregivers can note when they feel the most stress, and what has led up to that. Sometimes, it will be revealed that no one problem or behavior is overwhelming. Instead, the accumulation of small stressors without a break leads to difficulties. Solutions can then focus on how the caregiver can prevent the build up of stress, such as arranging for respite care.

The third treatment strategy is support. Clinicians can provide support directly with empathy for the caregiver and a nonjudgmental attitude. Interventions can also work to increase support and understanding from family and friends, and to gain more help from formal service providers. Clinicians can help families address the perceived and actual obstacles in respite services.

Three intervention modalities have been used with caregivers: one-to-one counseling; family meetings; and support groups. Each brings a different element to treatment. Short-term counseling can provide caregivers with the opportunity to explore their situation in depth and to consider the options and alternatives available to them in a supportive and nonjudgmental situation. Family meetings offer the opportunity to address directly areas of conflict and misunderstanding in the family and to build support and assistance for the primary caregiver. Support groups give caregivers the opportunity to discuss their situation with other people in similar situations. Groups may be an efficient means of sharing information and learning about new approaches and strategies.

Several studies document the effectiveness of these approaches. Whitlatch, Zarit, and von Eye (1991) found that caregivers receiving individual counseling and a family meeting had lower stress than people receiving only a support group or who were on a waiting list. In a series of studies, Toseland and his colleagues (Toseland, Rossiter, Peak, & Smith, 1990) have also found that counseling is more effective in the short run for relieving a caregiver's distress than support groups.

Mittelman and her colleagues (1993; 1995) developed a comprehensive intervention program that combines individual and family counseling during an initial four-month period, followed by sustained treatment in a support group. Caregivers in the treatment group had lower burden and distress and placed their relatives in nursing homes at a lower rate than people in a control group (see also, Whitlatch, Zarit, Goodwin, & von Eye, 1995).

These findings demonstrate the effectiveness of planned interventions designed to lower the stress of family caregivers. By increasing caregivers' skills in managing problems and stressors and bringing in new resources to support the caregiver whenever possible, clinicians can provide substantial assistance even in the face of a deteriorating condition. Through these interventions, caregivers can function as well as possible, while providing an optimal care environment for their relative. Timely use of these interventions may be cost-effective by preventing the breakdown of the family caregiving system, and encouraging a rational use of respite services, including institutional care when that is appropriate.

7.22.15 CONCLUSIONS

One of the major features of an aging society is that families are caring for disabled elders more often and for longer periods of time than ever before. There is considerable individual variability in how caregiving is handled and experienced, but it is typically stressful for the primary family helper and sometimes for the extended family network. The phenomenon of caregiving cannot be captured within a single measure of burden or stress. Rather, the many dimensions involved in the family's responses and the types of different stressors or problems caregivers experience have been observed. The stress of caregiving is an ongoing process, which evolves as the demands of care change and as caregivers develop new understanding, utilize different resources, or become overwhelmed by the unrelenting problems they face.

The challenge for the future is to find ways to support families so that they can provide high-quality, personalized care without excessive strain on themselves. The cost of care for social and health programs for the elderly has become an increasing problem for those countries with a significant proportion of their populations over age 65 years. As the number of elderly increase, cost-efficient means of providing care that do not sacrifice quality are needed. The responsibility for care cannot fall exclusively on families, because the burdens are too great, nor on society, since the cost will be too high. There need, instead, to be partnerships that find creative ways of sharing care, and which address the needs of both care recipient and caregiver. What shape those alliances will take, or the best models of working to support families, remain to be discovered. A small, but growing, clinical literature suggests that timely and well-conceived clinical interventions can be an important part of this partnership, helping families develop better strategies for managing a patient's disabilities and regulating the stress on themselves.

7.23.1 INTRODUCTION

Aging is associated with an increase in acute and chronic illness with serious consequences for daily living. To give the reader an idea of how prevalent these self-limiting conditions are in old age, the following empirical findings (Ebrahim, 1992; Kemp,1985) are used. The percentage of persons with arthritis increases from 1% for the less than 17 years old group to about 25% for the (noninstitutionalized) over 65 years old group. Heart conditions increase from 2.4% for the under 17 group to 23.4% for the over 65 group (these rates are significantly higher depending on the mode of data collection [self-reports versus medical expert rating; Jette, 1996). Visual and hearing disorders also increase dramatically with age. About one third of all persons 65 and older exhibits a significant hearing loss; about 8% suffer from severe age-related visual impairment. The prevalence of mental disorders also increases with age. The percentage of persons with major depression is about 11%; the percentage of elderly with at least some degree of dementia also hovers around 11%. Strokes, degenerative neurological disorders, pulmonary disorders, and most orthopedic disabilities increase with age at a similar rate. Also, there is convergent evidence that these prevalence rates increase dramatically from the young-old to the old-old and the oldest-old and are especially high in institutionalized settings (e.g., Jette, 1996; Suzman, Willis, & Manton, 1992; Schneekloth & Müller, 1995).

Whereas acute illnesses normally can be treated quite adequately in many old and very old persons, the burden of chronic illness (as well as the disabilities and functional losses in daily life that result from them) have become one of the most dramatic challenges for society, for gerontology in general, and for rehabilitation with elderly clients in particular. If our basic goal is to engender a "good" life into old age by fostering "active life expectancy" among the elderly (e.g., Crimmins, Hayward, & Saito, 1996), then rehabilitative work as the process of maximizing abilities after a disabling event (Kemp, 1996) gains crucial importance for the individual as well as for society.

Nevertheless, the burden imposed by chronic conditions, and the rehabilitative efforts to counteract them, deserve a highly differentiated analysis. Oversimplifying statements, whether positive or negative with respect to the power of rehabilitation to improve the lives of the elderly, are detrimental to research and can wreak havoc with the hopes and fears of the frail and chronically ill elderly and their families. On the one hand, the metamorphosis of gerontology from a decline and deficit view of old age toward a competence view that stresses the potentials and reserve capacities of old age has influenced significantly the field of geriatric rehabilitation. The body of empirical evidence underscores the success of rehabilitation in the elderly with respect to stroke, arthritis, cardiovascular disease, and falls (e.g., Andrews, 1987; Harris, O'Hara, & Harper, 1995; Kemp, 1985, 1996; Meier-Baumgartner, Nerenheim-Duscha, & Görres, 1992; Rubenstein et al., 1984; Schütz, 1993; Tallis, 1992). In addition, there is evidence that rehabilitation leads to better outcomes in the short and long run as compared to traditional medical treatment. On the other hand, convergent evidence from longitudinal and catamnestic studies show that the success of rehabilitation is tempered by everyday factors; further deterioration due to the underlying disease process, a lack of rehabilitation capacity in the homecare setting, poor ecological circumstances, or dependence-supporting behavior of the social environment (e.g., Horgas, Wahl, & Baltes, 1996; Meier-Baumgartner et al., 1992; Wahl & Baltes, 1993) can have a lasting, negative impact on the rehabilitation process.

With this in mind, it is accepted broadly in the academic field that rehabilitation with the elderly deserves additional research efforts in order to maximize its efficiency. For example, special problems that arise when treating the elderly must be considered, such as multimorbidity, concomitant cognitive impairments, reduced social networks, poor ecological conditions, longer time periods to regain certain functions, and lowered motivation ("I am too old; this is not worth the effort."). There is also general consensus within the professional field that rehabilitation truly deserves a multidisciplinary approach. The multiprofessional team should include high quality medical personnel, a psychiatrist, well-educated nursing staff, physical therapists, occupational therapists, speech pathologists, social workers, nutritionists, audiologists, and optometricians as well as experts in housing, design, and technical devices (Kemp, 1996; Saltz, 1995; Zeiss & Steffen, 1996). There is additional consent that rehabilitation of the elderly should take place in different settings such as the hospital, day-care center, home health care, and nursing home settings.

What is stressed in this chapter is that psychology as a research and applied field is essential to geriatric rehabilitation in all of these settings. The critical importance of addressing geropsychological and psychosocial issues in the field of geriatric rehabilitation is underscored by the two contrasting theoretical approaches briefly alluded to above. With respect to the competence view of rehabilitation in old age, the emergence and application of psychological intervention techniques such as behavioral or cognitive training programs has broadened significantly the scope of rehabilitation in different settings (in the nursing home setting in particular; e.g., Hussian & Davis, 1985; Wisocki, 1991). Also, there is general consensus that the differential success of rehabilitation programs has as much to do with underlying psychological and social issues (e.g., motivational issues, personality traits, sense of self-efficacy, ability to mobilize social support) as with the "objective" severity of the disease process. With respect to the limits and the fragility of rehabilitation success, the psychosocial perspective points to crucial aspects such as inadequate housing, certain neighborhood characteristics, and the attitudes and behaviors of significant others who may undermine the elderly's striving toward independent functioning (Baltes, 1996).

This chapter was written by two geropsychologists and thus presupposes that rehabilitation with the elderly can be effectively provided if a multidisciplinary and multiprofessional approach is applied. The task is to highlight the psychological and psychosocial perspective within geriatric rehabilitation. This is done in four sections: (i) general principles and geropsychological essentials of rehabilitation, (ii) psychosocial issues and strategies of rehabilitation with older adults (assessment issues, restoration of functional independence, cognitive retraining, psychotherapeutic intervention, motivation and compliance, role of social support, ecological aspects), (iii) psychosocial issues with respect to particular client groups (stroke, arthritis, the sensory impaired, demented patients), and (iv) final consideration of practical, research-related, and ethical problems of rehabilitation in old age.

7.23.2 GENERAL PRINCIPLES AND GEROPSYCHOLOGICAL ESSENTIALS OF REHABILITATION IN OLD AGE

7.23.2.1 General Principles

Rehabilitation is required whenever an impairment or a disability causes permanent, widespread disruption of the normal fit between person and environment. Central to understanding rehabilitation is the distinction between impairment, disability, and handicap (World Health Organization, 1980). Impairment is any loss or abnormality of psychological, physiological, or anatomical structure or function. Disability is any restriction, due to impairment, which limits the ability to perform an activity in the manner or within the range considered normal for a human being. Handicap is defined as a disadvantage resulting from an impairment or disability that limits or prevents the fulfillment of a role appropriate to a person's age, gender, social, and cultural circumstances. For example, a stroke might lead to pathological changes in the brain and quite often to unilateral paralysis (impairment). These stroke-induced impairments are responsible for deteriorations in walking, manual dexterity, memory, and speech performance (disability). These disabilities in turn lead to social consequences for the individual, preventing the person from participating in social roles and activities (handicap).

Rehabilitation can be regarded as a problem-solving and educational process aimed at reducing the disability and handicap experienced by someone as a result of disease, one that is always limited by the resources available (World Health Organization, 1980). Hence, rehabilitation is a set of procedures located between acute medical treatment and prevention. Of course, curable diseases should be treated medically, but whenever possible one should prevent disease instead of dealing with disabling and handicapping consequences. This statement is by no means trivial, as epidemiological data on stroke shows. Preventive measures are responsible for decreasing incidence rates for cardiovascular stroke (e.g., Svanborg, 1988; see also Fries, 1990). Nevertheless, rehabilitation is necessary in those cases where prevention or medical treatment are not effective. Hence, the focus of rehabilitative interventions is not the (underlying) disease but the functional level (e.g., Kemp, 1996). A medical diagnosis, that is knowledge about a certain impairment, does not necessarily imply knowledge about resulting disabilities and handicaps. Indeed, pronounced discrepancies in the emotional or functional outcomes between different patients suffering from "objectively" comparable diseases are more often the rule than the exception and require careful attention.

Rehabilitation is not only aimed at restoring the patients' rights, privileges, reputation, and/or proper condition, but also at realizing their potential, reablement, and resettlement (Ebrahim, 1992). However, rehabilitation with the elderly does not necessarily mean *restitutio ad integrum* (complete cure of disease, full elimination of handicap) but quite often *restitutio ad optimum* (improving functional capability and maximizing wellness). According to Williams (1984), rehabilitation in old age may be characterized as a set of techniques as well as a point of view or a philosophy. In accordance with this philosophy, the primary aim of rehabilitation is to restore an individual to their former functional status, or to maintain or maximize independent functioning (Lee & Itoh, 1990; Williams, 1994). Getting elderly clients to transfer themselves from the bed to a wheelchair may thus be a great rehabilitation success and have tremendous impact on the elderly persons' perception of life. At younger ages, the main goal of rehabilitation is the restoration of the individual's capacity to resume family and work roles. However, these are not necessarily the main goals of rehabilitation in old age. Rather, functional independence (self care and instrumental activities of daily living), the cultivation of leisure activities, and a sense of well-being, that is, improvement of life quality, are the main objectives of rehabilitation in old age (Andrews, 1991; Kemp, 1996; Mosqueda, 1996).

The general goals of geriatric rehabilitation are to control the underlying disease process, prevent secondary disabilities, restore functional abilities, facilitate the patient's adaptation, educate the patient regarding impairment, and modify or otherwise prepare the environment (Kemp, 1985; Saudan, 1990). The process of rehabilitation can be divided into five formal components (Ebrahim, 1992; Wade, 1992):

(i) *Assessment*. In addition to medical diagnosis, the identification, analysis, and measurement of problems in terms of disabilities and handicaps is an essential first step in the rehabilitation process.

(ii) *Planning*. This is extremely important in setting long-term, intermediate, and short-term goals. It is necessary to involve the patient as early and as intensively as possible in this planning procedure, since the acceptance of rehabilitation goals is important for motivation and compliance.

(iii) *Treatment*. Having identified the problems and formulated goals, the proper intervention should take place in order to reduce disability and minimize handicap. Treatment might consist of interventions aimed at the restoration of functional independence, cognitive retraining, psychotherapy or mobilization of social support.

(iv) *Care*. Although rehabilitation is aimed at restoring maximal functional capacity, very often care is necessary to support elderly persons and alleviate the consequences of disability.

(v) *Evaluation*. Great importance, although not a standard procedure in many rehabilitation settings, is the careful evaluation of the effectiveness of intervention which should consist of individual reassessment during or after the rehabilitation process (Görres, 1994).

Psychosocial and clinical-psychological issues play an important role in all of these components. Thus, rehabilitation should be based on a comprehensive psychological profile of the elderly client that includes neuropsychology evaluation as well as the assessment of personality, emotional-motivational functions and personal goals ((i) and (ii) above, assessment and planning). Individuals also need psychological support in order to cope with the existential crises normally following the onset of disability; treatment should focus on fostering behavioral, cognitive, and emotional changes, working on specific coping strategies, promoting self-esteem, improving family relations, and mobilizing other social network resources ((iii) and (iv) above; treatment and care). Finally, everyday life after rehabilitation should not only be seen in terms of functional gains but also in terms of life quality (subjective well-being, self-efficacy, and positive future expectations; (v) above; evaluation).

The goals of geriatric rehabilitation call for a thorough understanding of clinical psychology. Likewise, concepts from geropsychology and lifespan developmental psychology are fundamental to any rehabilitative endeavor. In the following pages, the theoretical foundations of geriatric rehabilitation are reviewed in some detail, before turning to psychosocial issues and strategies of rehabilitation with the elderly.

7.23.2.2 Geropsychological Essentials of Rehabilitation in Old Age

In practice, rehabilitation efforts will only be effective when essential concepts from gerontological and geropsychological research have been given due consideration. Because aging is a lifelong process, it is suggested that lifespan developmental psychology is crucial to gerontology and can contribute greatly to these conceptual essentials (e.g., Baltes, 1987; Lehr, 1993; 1996; Thomae, 1979).

First of all, the rehabilitation of the elderly should not be based on chronological age (or old age) per se but on aging. That is, the emphasis should lie on aging as a dynamic process which can be characterized, like any period of the lifespan, as the simultaneous occurrence of potentials and limits, gains and losses, continuity and change (Baltes, 1987; Thomae, 1979). A variety of studies within geropsychology and developmental psychology stresses the elderly person's potential for growth and development, contrasting starkly with a one-sided picture of mere decline (for overview, see Kruse, 1987; Lehr, 1996). Even when faced with severe competence losses, elderly persons are not reactive, helpless, or passive; instead, the majority of these elderly use a whole scope of coping strategies to deal actively and differentially with threats to their independence and life quality. Rehabilitation of the elderly should thus count on these coping capabilities to address severe illnesses or disabilities. Also, a major task of rehabilitation lies in the reactivation of the elderly person's potential to deal actively with their health threats, thereby regaining as much independent functioning in everyday life as possible. The strategy of selective optimization with compensation is a general adaptational tool to counteract detrimental health changes (e.g., Baltes & Baltes, 1990). From this point of view, rehabilitation in old age can be understood as the transmission of powerful compensation techniques and a mutual search for selective optimization opportunities (particularly in those cases in which the impairment and resulting disabilities can only be altered marginally). To conclude, rehabilitation in old age must base itself upon the insight that elderly persons possess certain fundamental physical and mental potentials (Kruse, 1992); agism must be scoured thoroughly from the rehabilitation effort.

Furthermore, the pronounced interindividual variability of the elderly must also be considered. Persuasive empirical indications from cognitive, personality, and social network research, show that heterogeneity is one of the defining criteria of the aged population (e.g., Nelson & Dannefer, 1992). The general implication for rehabilitation is that a highly individualized approach is necessary. In particular, there is reason to assume that the estimation of the rehabilitation potential deserves an individual point of view and can be significantly different even when the underlying disease (such as a certain type of stroke) is relatively similar between cases (Kruse, 1992). The mere fact that some individuals possess lifelong expertise in particular areas (whereas other individuals do not) may have tremendous implications for rehabilitation. The acknowledgment of variability also points to the need that rehabilitation efforts should not only focus on impairments and disabilities but also on remaining capacities and competencies.

Rehabilitative work must also view aging as an inherently biographical process (Lehr, 1996; Kruse, 1992; Thomae, 1996). Old age is a significant part of the individual biography and life course. Over the course of their lives, individuals develop particular attitudes and coping styles in dealing with everyday challenges and critical life events, such as the onset of severe health problems. Rehabilitation must not neglect these personal styles in dealing with illnesses; it may mean the difference between gaining a powerful tool to understand the idiosyncrasies of the elderly individual and jeopardizing the success of the rehabilitative effort. Individual development, biographical experiences, and evaluative standards also stress the importance of understanding the subjective interpretations assigned to competence losses in everyday life. It is commonplace in clinical work for subjective evaluations of illnesses, impairments, and disability to differ significantly from the ratings of physicians, clinical psychologists, and other professionals involved in the rehabilitation process. One consequence of these discrepancies can be that different goal attainment priorities between the elderly in rehabilitation and their professional surroundings emerge which may delay or even undermine rehabilitation success.

According to leading scholars in the field of lifespan developmental psychology (e.g., Baltes, 1987), aging must also be seen as a contextual phenomenon. One set of powerful factors is social influence. It is known from a body of classical work in gerontology that the course of aging is influenced by the way social networks have been arranged and maintained. Also that social contact means, on the one hand, mutual exchange, personal warmth, the opportunity to give and to receive, and in a sense even physical and cognitive training. On the other hand, social surroundings may hinder the elderly individual from using or exercising capabilities and may thus contribute to a decline in functioning. Rehabilitation should always consider the social embeddedness of aging processes, especially with regard to severe health problems. Thus, there is a need to integrate significant others in the rehabilitation process. These persons represent concrete links with the everyday world in which the elderly person will return; they may deserve training and education about how to interact with the elderly person after the rehabilitation program.

Aging is, however, also aging in place, that is, aging is also influenced by the physical environment (e.g., Lawton & Nahemow, 1973; Parmelee & Lawton, 1990; Saup, 1993; Wahl, 1992). Rehabilitation has to consider the simple fact that elderly faced with severe losses in competence do not normally age in clinical or institutional settings but in their own "world" at home. From this perspective, it is one of the challenges of rehabilitation to intervene as effectively as possible (which, in many cases, can only be done in a formal rehabilitation setting) but nevertheless as close to the everyday world of the elderly person as possible.

Finally, a very important construct in the rehabilitation of the aged stems from lifespan developmental psychology: plasticity (e.g., Baltes, 1987; Kruse, 1992). This term signifies that the course of aging is not predetermined or fixed, regardless of whether the process in question is one of "normal" aging or aging coupled with serious illnesses and disabilities. For example, cognitive training studies have underlined clearly the potential for significant gains which can sometimes exceed the level of untrained younger persons (Baltes, 1993; see also below). So-called control-enhancing interventions have proven their physical and psychological benefits even in frail elderly populations like nursing home residents (e.g., Rodin, 1986). Aging obviously is not a fixed and predetermined process but is subject to many different types of influences which may lead to differential outcomes. Rehabilitation may thus be regarded as one of the most powerful attempts to systematically influence aging organisms challenged by chronic disease processes.

In conclusion, the fact is emphasized that the fundamental principles and concepts of geriatric rehabilitation rest upon clinical as well as geropsychological insights. This should be kept in mind as some of the main psychosocial issues and strategies of rehabilitation in old age are discussed.

7.23.3 PSYCHOSOCIAL ISSUES AND STRATEGIES OF REHABILITATION IN OLD AGE

7.23.3.1 Assessment Issues

There is wide agreement that only comprehensive geriatric assessment (CGA) can serve as a basis for successful rehabilitative work with the elderly (e.g., Stuck, Siu, Wieland, Adams, & Rubenstein, 1992). Although not expressed explicitly in this widely used term, the assessment of psychological functioning is as a very important part of CGA. Furthermore, geropsychological knowledge and research can contribute to the shortcomings of CGA as it is commonly conducted in most rehabilitation settings. It should be mentioned that the aim of this section is not to give a complete overview of cognitive and neuropsychological assessment (which undoubtedly is also critical with respect to geriatric rehabilitation and its outcomes; see Chapter 7, this volume; see also Franzen & Martin, 1996; Rentz, 1991); instead, issues beyond the assessment of cognitive functioning will be discussed (cf. Lawton & Teresi, 1994). Comprehensive geriatric assessment has at least three major tasks: (i) to measure individual functional capacity, that is, losses as well as competencies at the beginning and during the course of the rehabilitation process; (ii) to contribute to the planning and prognosis of rehabilitation; and (iii) to serve as a tool for quality assurance and evaluation. To fulfill these tasks, CGA is basically aimed at the differential description of disease-related impairments to everyday life and functioning (see again the functional approach as one general principle of rehabilitation, above).

7.23.3.1.1 Activities of daily living and instrumental activities of daily living

One core issue of CGA is thus the estimation of decline and competence in activities of daily living (ADL) of varying complexity. In most research and practical work, basic ADL such as the capacity for eating, washing, or dressing are differentiated from instrumental activities of daily living (IADL), such as shopping, phone use, banking, or the intake of medications. A whole range of rather similar scales for the measurement of ADL and IADL can be found in the psychological literature. With respect to the basic ADL, the Barthel index has found wide use in geriatric rehabilitation (Mahoney & Barthel, 1965); prototypical IADL are represented in the widely applied Lawton and Brody scale (Lawton & Brody, 1969).

All of these scales are short and easy to apply. However, there are also problems: for one, the assessment of functional capacity is based mostly on face validity and still lacks theoretical foundation. It is thus strongly argued for closer links between the ADL/IADL literature (including their respective assessment devices in the clinical setting) and emerging theoretical and empirical research on everyday competence (e.g., Baltes, Maas, Wilms, & Borchelt, 1996; Willis, 1991, 1996). In particular, this latter work supports the notion that everyday competence depends heavily on personal and environmental variables that lie beyond chronic illness conditions such as cognitive performance and environmental barriers. One assessment implication of this insight is the need to "diagnose" the physical environment and always interpret a given degree of competence or impairment in everyday functioning (as assessed based on the common ADL/IADL approach) as the result of a transaction between personal capabilities and environmental circumstances. Furthermore, the existing everyday competence literature suggests that basic ADL and IADL are fundamentally different: the former are closely linked to basic physical capacity, whereas the latter depend heavily on motivation and socialization (e.g., preparing meals in elderly men). Second, functional capacity and thus the assessment of everyday performance should not only be focused on ADL and IADL; the capacity to solve everyday problems effectively (Willis, 1996) and to perform leisure activities in the social and nonsocial domain deserve to be assessed as well (e.g., Baltes et al., 1996) in order to gain a comprehensive picture of the everyday implications of chronic disablement.

7.23.3.1.2 *Performance vs. reserve capacity*

ADL/IADL scales can measure performance in functioning but not remaining reserve capacity, that is the individual's potential for further growth, which can be activated during the rehabilitation process. Although there is no *via regia* to approach this issue (which is a crucial one for planning the rehabilitation process), one important aspect in this regard is to consider the personality characteristics of the elderly client (see below).

Obviously, it would not make very much sense to expect that the reactivation of remaining reserve capacities always occurs under ideal personal and environmental conditions. Although it is always possible to alter personality (e.g., by psychotherapeutic intervention) or modify the social and physical surroundings, an adequate and realistic estimation of the current personal and living situation of the elderly client is indispensable. For example, anamnestic exploration should not only focus on the medical history but also on personal motivations, biographical key experiences with relevance for the coping with the current rehabilitation process, subjective evaluations of personal competencies, and coping styles (see the geropsychological essentials of rehabilitation described above). Another important area encompasses personality variables such as introversion—extraversion or anxiety. Both of these variables probably influence the rehabilitation process in different ways. For example, the personality characteristic of introversion versus extraversion may strongly influence the motivation to regain mastery over daily living tasks. Also, trait as well as state anxiety may undermine rehabilitation and transferral to the home situation if not taken seriously.

The results of all of these assessments can be crucial for the development of the final rehabilitation plan. Rehabilitation should always be done in close cooperation with the individual because the implementation of relevant goals and strategies depends heavily on the client's insight, motivation, and compliance. According to the contextuality of the aging process and the docility of the chronically ill organism to "pressing" environmental conditions (as stated quite early on in the so-called Environmental Docility Hypothesis, see Lawton & Simon, 1968), assessment should also include the description of the physical home environment (see, for example, Regnier & Pynoos, 1987). Also, the measurement of rehabilitation outcome should be regarded as more than mere ADL/IADL improvement. The basic aim of rehabilitation to contribute to life quality in general deserves the assessment of subjective well-being, depressivity, or of mood states as well (Kemp, 1996).

7.23.3.2 Restoration of Functional Independence

7.23.3.2.1 *Functional independence as basic objective of geriatric rehabilitation*

The restoration of functional independence can be regarded as one of the most important, though not the only, objective of geriatric rehabilitation. Independent functioning in daily life is highly valued within (Western) society; hence, the preservation or restoration of independence represents one of the most important life goals of most elderly. Basic ADL functions to be considered are self-care (such as eating, drinking, dressing, grooming, washing, and controlling urination and bowel movements) and mobility (getting in and out of bed, chair, or toilet, walking, and climbing stairs). For community dwelling elderly persons, being capable of performing instrumental activities of daily living is extremely important (doing household chores, shopping, cooking). There is also reason to assume that independent functioning in these daily living tasks is associated closely with related personal variables such as perceptions of control, self-efficacy, and competency; thus, personal autonomy can contribute much to good psychological adaptation in the course of aging.

Obviously, the majority of efforts within the multiprofessional team, such as physical or occupational therapy, is aimed toward improving functional capacity. It must once again be emphasized here that this goal does not necessarily entail the restoration of full independence. As Kemp (1996) has put it, to manage the step from "maximum assist" to "partial assist" can mean a dramatic gain for the elderly individual as well as their social environment. Most importantly, this "small" step can enable the individual to remain in a private household situation and to avoid relocation to a nursing home setting. Reliance upon functional criteria in rehabilitation is reliance upon personal variables, and the latter repeatedly have proven themselves superior to mere medical diagnoses in the prediction of important outcome variables (e.g., nursing home entry, daily life quality, life satisfaction, and even mortality; e.g., Kemp, 1996).

7.23.3.2.2 Contributions from clinical geropsychology

It would be shortsighted, however, to view the restoration of independence solely from a physical training perspective. Although bodily functions such as gross and fine mobility are important for performance of ADL and IADL (and should, thus, be trained by different means during geriatric rehabilitation), there is reason to assume that psychological factors are important as well. One factor is cognitive performance (e.g., Baltes et al., 1996; Willis, 1991); cognitive retraining can contribute significantly to the regaining of everyday competence. Also, since striving toward independence has much to do with the motivational and goal-directedness of each client, counseling and psychotherapeutic interventions can maximize the effects of medically-oriented treatments such as physical therapy and training in basic mobility (see respective sections below).

The restoration of functional independence in daily living tasks is also a prototypical case for the effectiveness of behavioral modification techniques based on social-learning principles, that is, it underscores the worth of a genuinely psychological intervention strategy. A whole body of research has demonstrated that such techniques (e.g., the use of different reinforcement procedures) can contribute significantly to the maintenance or restoration of functional independence in the elderly (e.g., Hasselkus, 1989; Smyer, Zarit, & Qualls, 1990; Wisocki, 1991). These approaches have particular rehabilitative value in institutionalized settings. Not long ago, the institutionalized elderly more or less led passive, sheltered lives under custodial care. In the 1990s, there is a basic consensus that institutions should be able to promote successful aging; they are not only expected to provide a secure and prosthetic environment, but also to stimulate autonomy (Baltes, Wahl, & Reichert, 1991). As was shown in a research program, the etiology and maintenance of dependence in institutions is related closely to the social environment, that is, the dependence-supportive behavior of staff and others in institutionalized settings. The systematic change of these interaction patterns by means of cognitive and behavioral training with staff led to a significant increase in the independent functioning of nursing home residents (e.g., Baltes & Wahl, 1996). Because a strong tendency has been found toward independence-supportive behavior within the home health setting (e.g., Baltes & Wahl, 1992), rehabilitative efforts based on cognitive and behavioral motivations should not be reserved solely for institutional settings.

Functional loss is thus not only a characteristic of the person but always a feature person–environment interchange. Naturally, this fact carries implications for rehabilitation. Disability may be reduced by increasing personal competence, changing situational demands, or employing effective compensation strategies (e.g., simplification or redesign of the task; see also Dixon & Bäckman, 1995). Due to practical constraints in terms of time, effort, or money, rehabilitation aimed toward the restoration of functional independence thus is forced frequently to make a decision of what is more promising, that is, to change the person, to change the environment, or to change the task performance itself. Assessment issues like the ones described above (i.e., information pertaining to the elderly client as well as their social and physical environment) is particularly helpful in selecting the best possible from these alternatives.

7.23.3.3 Cognitive Retraining

Cognitive capacity can be divided into two broad ability categories; fluid intelligence and crystallized intelligence (Baltes, 1984; Cattell, 1971; Horn & Hofer, 1992). Fluid intelligence, also called cognitive mechanics, encompasses the most basic cognitive processes and is measured mostly using memory tasks, problem-solving tasks, or perceptual speed tasks. Crystallized intelligence, or cognitive pragmatics, encompasses the experience and knowledge-related parts of cognitive capacity and is measured using knowledge or fluency tasks. Several studies have shown a decline in fluid intelligence already by middle age, while crystallized intelligence shows stability in adulthood and declines markedly only in old age (Salthouse, 1991; Schaie & Willis, 1993; Smith & Baltes, 1996). Such cognitive decline in old age seems characteristic of normal aging; it is not confined to elderly persons with a diagnosis of dementia (Reischies & Lindenberger, 1996), although it is more severe in such cases. Dementia is a syndrome due to brain disease in which there is impairment of multiple higher cortical functions, including memory, thinking, orientation, comprehension, learning capacity, and language (see also Chapter 10, this volume). The prevalence rates for dementia range from 3–7% for the population over 65 years, and increases dramatically with advancing age (Cooper, 1991a). Given cognitive decline in old age, and especially in the case of dementia, it is worth investigating whether (re)training might possibly help with these age- and/or disease-related losses.

7.23.3.3.1 Intelligence training

Experimental studies have demonstrated that cognitive interventions in old age are successful (Baltes & Lindenberger, 1988; Baltes,1993). In several studies, it could be shown that the cognitive performance of elderly people is modifiable (Baltes, Sowarka, & Kliegl, 1989; Blieszner, Willis, & Baltes, 1981; Willis, Blieszner, & Baltes, 1981). In these studies, the emphasis of training was on explaining and practicing rules for solving figural relations tasks and inductive reasoning problems. Even with few (5–10) training sessions, elderly participants increased their test scores in post-intervention assessments. Despite the gains achieved in cognitive training, it seems necessary to ensure the generalizability of these interventions (e.g., training in inductive reasoning, deductive reasoning, fluency, and memory techniques should help elderly people solve practical, everyday problems). Furthermore, the rehabilitative power of combining cognitive training with other intervention strategies (e.g., psychomotor training components, training in everyday problem solving) deserve consideration (see for instance Butler & Namerow, 1988, and their differentiation between cognitive retraining, aimed at improving cognitive "micro-processes," and skill acquisition training as a functional "macro-treatment" with greater rehabilitation impact; e.g., Oswald, Rupprecht, & Gunzelmann, 1998). Elderly persons at risk of dementia or even at low to moderate levels of dementia also can profit from cognitive training, although their training gains are much lower than those of healthy persons (Bäckman, Josephsson, Herlitz, Stigsdottir, & Viitanen, 1991; Baltes & Sowarka, 1995). Plasticity appears to be greatly reduced in dementia, even at the onset. Therefore, it has been argued that cognitive training might be a useful diagnostic tool for the early detection of dementia processes (e.g., the testing-the-limits approach; Baltes, Kühl, Gutzmann, & Sowarka, 1995).

7.23.3.3.2 Memory training

Decrease in memory capacity seems to be a marker of aging, at least in the subjective conceptions of elderly people (Abson & Rabbitt, 1988). More equivocal support for memory decline in old age has been reported (Fleischmann, 1989; Kausler, 1991). Nevertheless, memory training with older participants has been tested carefully. A wide variety of memory tasks (recognition, free recall, or pair-association learning) and memory strategies (including diverse mnemotechniques like verbal categorization, elaboration, visual imagery, and the method of loci; Fleischmann, 1982; Yesavage, Lapp, & Sheikh, 1989) have been examined. In the majority of these experiments, the effects of memory training in elderly people are positive. Interestingly, memory training which combines memory strategies with reattribution training, in order to reduce exaggerated achievement levels and change attribution patterns for success and failure, might help elderly people most (Lachman, Weaver, Bandura, Elliott, & Lewkowicz 1992; Weinert & Knopf, 1990). Memory training can be effective in mildly demented elderly persons as well (Ermini-Fünfschilling & Meier,1995). Still, the generalizability of memory training from laboratory settings to everyday memory functioning has yet to be proven (see also Camp, et al., 1993).

7.23.3.3.3 Reality orientation training

Persons suffering from dementia can profit greatly from training in time and space orientation (Kaschel, Zeiser-Kaschel, & Mayer, 1992). Dementia not only affects higher order problem solving but, in later stages, it also impedes basic functions like orienting in time (year, season, day of the month), space (rooms of apartment or institution), and contacting communication partners (staff members, family). Basic cognitive training encompasses orientation in time and space; also, reinforcement of the mechanics and pragmatics of intelligence may be included depending on the cognitive status of the rehabilitation client (e.g., Bäckman et al., 1991; Koh et al., 1994; Little, 1991; Rentz, 1991). Speech and communication therapy might also be very helpful in demented patients or patients suffering from stroke (Sarno, 1984; Jordan, Worral, Hickson, & Dodd, 1993). However, persons with dementia do not only profit from cognitive training in the strict sense of the word. A reactivating occupational therapy program can complement functional rehabilitation in long-term geriatric inpatients with slight to moderate dementia (Bach, Bach, Böhmer, Frühwald, & Grilc, 1995).

To summarize, it can be stated that although younger persons profit even more from cognitive interventions, intelligence and memory training are effective in the healthy elderly. Relatively smaller training effects have been demonstrated in the demented elderly, also. Despite the successes reported in such research, cognitive interventions which fit the everyday needs of elderly people are still the exception. Practical problem solving like reading (and understanding) public transportation schedules might be a good example (Schaie & Willis, 1986). It is also unclear whether cognitive interventions have substantial, long-term consequences. Especially in the case of dementia, however, such interventions might support the person and their caregivers in getting along with the ever-increasing complexity of everyday life.

7.23.3.4 Psychotherapeutic Intervention

Disability and handicap mean a more or less sudden decrease in the functional capacity of the elderly person; this may severely threaten mental balance and stability. Most threatening for elderly persons is the anticipation that living conditions must be changed dramatically in the near future (such as the relocation to an institutional setting) or that future life will only be possible at the cost of great dependency upon others. The psychological burden of losing one's own independence is compounded by the anticipation of becoming a burden to others, thereby negatively influencing the life course of loved ones. There is also broad evidence in the depression literature that severe physical chronic conditions are correlated significantly with depressive episodes (e.g., Schulz & Williamson, 1993; see also Gatz, Kasl-Godley, & Karel, 1996); in other words, besides functional impairments, the identity and self-esteem of the handicapped person are also threatened.

Geriatric rehabilitation seldom calls upon psychotherapy to play the role it should in addressing the psychological crisis experienced by the disabled elderly. Rehabilitation should, however, rise to meet the challenge of helping the elderly person to cope successfully with their disabilities and handicaps. To restate the argument: psychologists have more than only diagnostic tasks to fulfill in geriatric rehabilitation.

Because of the time limitations of normal rehabilitation efforts, individual and group psychotherapy based on a cognitive-behavioral philosophy seem particularly promising to deal with these problems, especially with depressive episodes (Hartke & Horowitz, 1991; Smyer, et al., 1990). However, treatment of depression is only one focus. There are further challenges having to do with the optimization of the rehabilitation success as well as with the maintenance of outcomes, particularly when transitioning from the hospital to the home situation. One task is to enhance motivation in certain clients, particularly in those who have started rehabilitation based on an externally induced motivation ("My wife suggested to try it."). Another approach with special importance for the maintenance of rehabilitation success in the "real world" employs coping skills training (see also Rodin, 1986). This powerful preventive tool serves to develop strategies and train the individual to deal with daily hassles, stress, and possible failure, all of which occur frequently after returning home.

Also, counseling with the goal of enhancing feelings of self-efficacy and competence (despite severe disabilities) may be an important task for clinical psychologists in geriatric rehabilitation. In some cases, psychological support with the goal of learning to accept irreversible losses is critical as well. Social competence training may be particularly helpful in those elderly living alone and running the risk of becoming still more isolated after the onset of chronic illnesses and the disabilities and handicaps they entail. Finally, counseling the relatives of the elderly clients (particularly those living with the client) may be crucial for the maintenance of rehabilitation success. If it is true, as research shows, that a dependence-supportive interaction pattern prevails in the private household setting (as well as in institutional settings), then the counseling and education of the persons in the elderly client's social sphere obviously becomes most important (Baltes & Wahl, 1992; Wahl & Baltes, 1993).

A point frequently not taken as seriously as it deserves should be mentioned at the end of this section, namely, rehabilitation with the mentally ill elderly (e.g., Häfner, 1986; see also Carstensen, Edelstein, & Dornbrand, 1996). The special rehabilitation needs of the mentally ill (e.g., those suffering from major depressive disorders or psychotic disturbances) are seldom acknowledged, even among professionals. Researchers and professionals in geriatric rehabilitation should be encouraged to give this subgroup of the chronically ill elderly the attention they rightfully deserve.

7.23.3.5 Considering Motivation and Compliance Issues

It is a truism to state that the motivation and compliance of the elderly person are necessary conditions for successful rehabilitation (King & Barrowclough, 1989; Ellul, Watkins, Ferguson, & Barer, 1992; Hartke, 1991; Trezona, 1991). The elderly person has to be convinced that participating in a rehabilitation program is worth the effort and cost. Hence, it is necessary to understand the personal attitudes and intentions of the person before starting the rehabilitation process (see, for example Wiesner & Tesch-Römer, 1996).

7.23.3.5.1 Motivation

Although the problem of motivating the elderly patient is often mentioned in the rehabilitation literature, rarely are specific measures for increasing motivation described. Quite often, elderly people are convinced that rehabilitation is not worthwhile, that improvement is impossible, that too much effort is required, or that the results of rehabilitation might threaten the current safe (albeit dependent) life situation. Improving motivation can be achieved through communication with the elderly person before and during rehabilitation, giving credence to individual goals, and simplifying steps needed to achieve rehabilitation objectives (Kemp, 1985). Specifically, changing pessimistic self-efficacy beliefs, strengthening self-esteem, increasing optimism, and exploring "possible selves" might be helpful in increasing motivation for rehabilitation (Guthrie & Harvey, 1994). Important aspects of the rehabilitation process that might enhance motivation are information (What should one know about the intervention?), choice (Which options are available?), goal-setting (What are long- and short-term goals?), attention to emotional needs (What does the disability/handicap mean to the person?), and dealing with social anxieties (What do other people think/expect?). Finally, it should be noted that lack of motivation could also be due to an endogenous depressive disorder. Similarly, motivational deficits can occur due to reactive depression following loss sustained in the initial illness or even a specific brain disease (like frontal lobe disorder, Vanderpool, 1984). In these cases, specific therapeutic interventions might be necessary.

7.23.3.5.2 Compliance

It is not enough that the person is motivated to start rehabilitation, they must also comply with the rehabilitative process, which can take weeks or months. Problems during the intervention process may result from low motivation, psychosocial crises, or cognitive decline (e.g., memory problems). Hence, elderly persons in rehabilitation should be helped to maintain a schedule if necessary. This can be achieved by keeping short-term goals clear and giving simple instructions for rehabilitation procedures. Moreover, motivation should be maintained by regularly encouraging and reinforcing the rehabilitation progress. Examples for the importance of compliance issues can be found in prosthetics use (Cameron & Quine, 1994), implementing safety features at home (El-Faizy & Reinsch, 1994), and continence training (Fonda, 1991).

7.23.3.5.3 Impact of the social network on motivation and compliance

The social network of the patient is very important in rehabilitation motivation and compliance. Motivation is not a personal characteristic, but a product of interpersonal interactions. Hence, motivation can be influenced significantly by rehabilitation staff, family members, and community services (Tucker, 1984). An example might be shaping the self-care behavior of elderly nursing home residents via social feedback from staff members (Baltes, Burgess, & Stewart, 1980; Baltes, Kindermann, & Reisenzein, 1986). It should be noted, however, that it is difficult for health professionals in institutional settings to rate rehabilitation motivation; rehabilitation decisions can be facilitated by describing specific behaviors, like mobility, self-care, independence, and socialization (King & Barrowclough, 1989).

Before beginning a rehabilitative intervention, it would seem useful to instill a sense of confidence in the elderly client, to persuade them that the long road ahead is not so very difficult and well worth the effort. Motivation is a complex product of the interaction between a person's values, the values held by significant others, history, talents and interests, personality, and treatment setting. As a rule of thumb, one should emphasize that if a derogatory, devalued label is applied to the person (either by the person or by the social network), rehabilitative efforts will fail; conversely, if the person is given positive feedback, the individual's motivation for rehabilitation will be enhanced.

7.23.3.6 The Role of Social Support

Social relations change with advancing age. The chance of living with a partner, especially for women, decreases, the size of the social network shrinks, and loneliness increases with advancing age (Wagner, Schütze, & Lang, 1996). Elderly people living in institutions are especially vulnerable to accumulated risk factors for social isolation and loneliness. Nevertheless, important aspects of the "social convoy" remain stable even in old age (Antonucci, 1985). Most elderly people have good relations and frequent contact with children and grandchildren, and elderly people at all ages name friends, acquaintances, or neighbors as parts of their social network. Moreover, elderly people are not solely receivers of social support; they also give support to members of their social network. At this point, one should distinguish between emotional and instrumental support. In rehabilitation, one might inquire regarding what role social support plays in the well-being of the disabled elderly, and how social support could be mobilized for the purpose of rehabilitation.

7.23.3.6.1 Effects of social support

There can be no doubt that social support, whether instrumental or emotional, helps the elderly individual cope with chronic illness and disabilities that remain even after the best rehabilitation efforts (e.g., Antonucci & Jackson, 1987; Silverstone, 1984). Several studies show that social support has positive effects upon a broad range of handicaps and in various rehabilitation settings. Chronic pain patients with supportive families tend to report less pain intensity, less reliance on medication, and greater activity levels than patients with non-supportive, disharmonic families (Jamison & Virts, 1990). In stroke patients, emotional support and moderate degrees of instrumental support are related to positive outcomes and recovery (Glass & Maddox, 1992). However, social support might be dysfunctional as well. Too much instrumental support might hinder the recovery of stroke patients. Hence, the positive and potentially negative sides of social support deserve consideration in this context. On the one hand, social partners should be integrated into the rehabilitation process as early as possible, since they are able to contribute significantly to the restoration and maintenance of functional independence of the elderly client. On the other hand, social interactions can also become detrimental to the elderly when social partners tend toward overcare (e.g., Baltes & Wahl, 1996), or care giving situations evoke an overflow of problematic psychodynamic elements (see Pearlin, Aneshensel, Mullan, & Whitlatch, 1996).

7.23.3.6.2 Mobilizing social support

Social relations (and the sources of social support) can be divided into informal and formal support givers (Silverstone, 1984). Among the informal support givers are spouses (especially wives), children (especially daughters), friends, and neighbors. The existence of a possible support giver does not necessarily mean that an elderly handicapped person receives help from network members. This is of some importance, because without some type of informal support, a return to the patient's home in the community might be very difficult. The burden (and the support) of the caregivers should also be acknowledged (see Chapter 22, this volume). The support offered by family (and friends) should be supplemented by formal support givers, such as primary health care, rehabilitation services, social workers, homemakers, meals-on-wheels, and so on. It should also be acknowledged that the (possibly short) acute phase of illness is usually followed by a recuperative phase and a (probably long) maintenance phase. Allocation of formal community services should depend on the needs and prospects of the care recipient and amount of resources available. Even in the case of psychiatric disorders, day-care, outpatient care, and community-based care can be implemented (Cooper, 1991b).

Hence, whenever possible, the global goal of rehabilitative efforts is to discharge elderly patients into the community, that is, back to their former, everyday living situation. Therefore, the mobilization of social support is important for helping the elderly person to live as independently as possible but with as much help from social partners at home as necessary. Living in the community and in one's own home means getting permanent and everyday support, even if this support takes the form of "small" gestures and signs from the neighborhood (Wagner, Schütze, & Lang, 1996).

7.23.3.7 Ecological Aspects of Rehabilitation

Although a "gestalt switch" from the elderly person to the environment took place in the 1960s and 1970s (see, for example, Lawton & Nahemow, 1973), gerontology in general and geriatric rehabilitation in particular is still very "person centered." From its inception, environmental gerontology persistently has considered the elderly person's surroundings as protective or risk factors for independent functioning. Of particular relevance here is the Environmental Docility Hypothesis, according to which the elderly suffering from competence losses and chronic conditions are particularly prone to environmental characteristics (e.g., Lawton, 1982; Lawton & Simon, 1968). A few simple statements can be emphasized. Independence in self-care always means independence in a certain bathroom environment (with certain supportive or constraining conditions). Independence in meal preparation always means independent meal preparation in a certain kitchen environment with specific features and equipment. Finally, independence in shopping always means independence within a certain neighborhood or meso-environment with supermarkets of varying proximity.

7.23.3.7.1 Person–environment fit as critical for rehabilitation

There is thus good reason to assume that discrepancies between the competence profile of the elderly person and the environment can undermine even the best person-centered rehabilitation effort (e.g., Lawton, 1982; Olbrich & Diegritz, 1995). This is true, for instance, with respect to the eastern part of Germany (the former German Democratic Republic), in which housing conditions are still significantly worse compared to those in the western part. As empirical analyses have revealed, discrepancies on measures of daily competence are at least in part caused by poor living environments within and outside the home (e.g., long distances to supermarkets and pharmacies) that are prevalent in the eastern regions of the country (Olbrich & Diegritz, 1995; Schneekloth & Potthoff, 1993).

Thus, rehabilitation should always be aimed at both training the elderly client to cope with environmental challenges and changing environmental features to suit their profile of deficits and competencies (e.g., Regnier & Pynoos, 1987; 1992; Parmelee & Lawton, 1990). Rehabilitation may thus be defined as the attempt to reduce all possible discrepancies between personal competence and environmental challenges by focusing on the person and their physical environment.

7.23.3.7.2 Considering objective and subjective environmental aspects within the everyday world

One should also note that the physical environments of the elderly are more than mere objective surroundings which vary in the amount of support they offer. Environments may also be viewed as materializations of personal biographies and as extensions of the personal self (Wahl & Oswald, in press); this concept is particularly relevant for the great number of elderly individuals who do not live for decades at the same location. Thus, alterations may indeed be helpful and necessary for the rehabilitation outcome from an objective perspective, but not from the elderly client's point of view. Geriatric practitioners should take these subjective evaluations seriously; the elderly individual's decision to refrain from modifying their home environment must be considered to be a valid choice, even though it might lower independence in daily functioning in the long run. Furthermore, elderly persons should not be seen as mere pawns of their environmental conditions. The creativity with which the elderly (particularly those suffering from chronic conditions) use their potential for compensation is very impressive; they demonstrate consistently a high degree of "proactivity" in adapting themselves to their living environments and vice versa (Lawton, 1989; see also Wahl & Oswald, in press).

The ecological approach to geriatric rehabilitation may be used to illustrate another basic issue. Environmental gerontology and psychology have always stressed the importance of remaining as close as possible to the everyday world of their subjects (see for example the concept of behavior setting proposed by Barker, 1968); likewise, rehabilitation efforts should also demonstrate a good measure of "ecological validity" (Wahl & Baltes, 1993). Rehabilitative work, particularly when it takes place in a hospital setting, should do its utmost remain close to the "life world" of the elderly individual; this is the most promising way to ensure the maintenance of rehabilitation outcomes in the home world.

7.23.3.7.3 New technologies and their rehabilitation potential

Finally the issue of old age and technology should be mentioned briefly, particularly so-called new technologies (e.g., Bouma & Graafmans, 1992; Charness & Bosman, 1990). What is emphasized here, is that there is no reason to assume that elderly persons are unable or unwilling to use new technologies. Instead, these devices could become major parts of the rehabilitative process in a variety of ways. For example, shopping via a home computer may be advantageous to the elderly person with significant impairment in mobility, and contribute greatly to self-efficacy and feelings of control. E-mail services or fax devices can facilitate the maintenance of social networks and social exchange, particularly when social isolation results from disablement.

7.23.4 PSYCHOSOCIAL REHABILITATION ISSUES WITH RESPECT TO PARTICULAR CLIENT GROUPS

Rehabilitation must change to suit different kinds of handicaps. With this in mind, four client groups, namely stroke patients, arthritis patients, the sensory impaired elderly, and demented elderly, are discussed in more detail in this subsection. Although it is clear that rehabilitation programs exist for other age-related handicaps as well (e.g., amputation, Marmann, 1994; falls and hip fracture, Campbell, 1992; Felsenthal & Stein, 1990), there are at least three reasons to concentrate on these four target groups. First, each of these illnesses represents a chronic condition that is highly prevalent in the population at large. Second, arthritis, sensory impairments, dementia, and to a lesser extent, stroke, do not receive the attention within geriatric rehabilitation which they deserve. Third, each patient group poses a significant, yet unique challenge to the rehabilitation professional.

7.23.4.1 Stroke Patients

Cerebrovascular diseases belong to the most prevalent diagnoses in old age (Steinhagen-Thiessen & Borchelt, 1996). Cerebral vascular accident (stroke) constitutes the third leading cause of death in the United States (following heart disease and cancer). About one third of stroke victims will die within the first three months after the stroke. Symptoms of stroke can be partial or complete paralysis, urinary incontinence, difficulties in swallowing, aphasia, and losses in memory and other cognitive functions (Wade, 1992). The functional consequences of stroke are often serious and concern overall physical ability (activities of daily living), walking, dexterity, and communication (Gibson & Caplan, 1984). Very often mood changes occur; many stroke victims develop depressive symptoms which might negatively influence the rehabilitation process (Goldberg, 1984). Early medical treatment of the stroke is extremely important, and it seems that specialized stroke units reduce morbidity and mortality among stroke victims (Langhorne, Williams, Gilchrist, & Howie, 1993). Once the clinical state has settled, one can expect a period of rapid recovery over the first 2–3 weeks, followed by slower but continuing improvement over the next five months (Wade & Langton-Hewer,1987). There is much debate whether functional improvement occurs after that, but some studies show that continued rehabilitative efforts might be helpful (Dam, et al., 1993). More information on pathophysiological changes can be found in geriatric textbooks (Abrams, Berkow, & Fletcher, 1990; Brocklehurst, Tallis, & Fillit, 1992; Evans & Williams, 1992; Pathy, 1991).

7.23.4.1.1 Critical issues of rehabilitation

Rehabilitation should start immediately after the onset of stroke. From the beginning, the patient should be mobilized and encouraged to be as independent as possible. Rehabilitation efforts should also be directed toward communication disorders, upper extremity function, and bowel and bladder care. Assessment is also crucial to stroke rehabilitation; detecting disabilities, discovering the relevant impairments, determining prognosis, planning the intervention process, and evaluating rehabilitation progress are the tasks of the interdisciplinary stroke rehabilitation team (Kruse, 1992, 1995; Rustemeyer, 1983). Physicians are responsible for medical diagnosis and treatment, although no effective medical therapy can ensure complete recovery from stroke. Hence, a variety of professions are involved in stroke rehabilitation. Physiotherapeutic exercises, such as those which improve range of motion, muscle strength, and endurance, are necessary for dealing with muscle spasticity and improving functional performance (Lee & Itoh, 1992). The Bobath method of treatment has been very influential in stroke rehabilitation, emphasizing the suppression of abnormal postures and movements before normal motor patterns are practiced (Bobath, 1971). Although physiotherapy should start early, even late physiotherapeutic intervention (12 months after stroke) can improve mobility (Wade, Collen, Robb, & Warlow, 1992). Occupational therapy is directed at training compensatory techniques for performing activities of daily living (Hasselkuss, 1989). Speech therapy is aimed at supporting stroke patients to overcome communication problems (Lehmann, 1992; Sarno, 1984; Vignolo, 1964).

Psychologists might carry out several important tasks in stroke rehabilitation. Changes concerning alterations in intellect, personality, and emotional behavior deserve attention in the diagnostic process as well as in psychotherapeutic interventions aimed at the elderly person or their social environment (Kruse, 1984). First, psychological and neuropsychological diagnostics are genuinely psychological tasks and highly relevant for assessing the specific problems of stroke patients (Lawton & Teresi, 1994). Since many patients suffer from depressive symptoms, psychological counseling might help the patient to cope with the losses resulting from the stroke and to recover from depressed mood. Clinical psychologists working with stroke patients need to plan realistic short-term goals, provide structure for working sessions, and carefully confront the patient with the denial of disability (Goldberg, 1984). Also group therapy with other stroke patients and family therapy, involving spouse and other family members, might be helpful.

Ideally, stroke patients should be able to return home after rehabilitation. It is necessary to plan carefully the discharge of the patient, involving family and community-based services as far as possible. If necessary, the patient's home should be altered to accommodate the needs of the stroke patient. For family members, caring for a relative suffering from stroke and its consequences is highly distressing; hence, community services should not only focus attention toward the neuropsychological aspects of stroke patients, but also toward the social functioning of caregivers who support them (Anderson, Linto, & Stewart-Wynne, 1995).

7.23.4.1.2 Effects of rehabilitation and challenges in the future

Since the treatment of stroke in older patients is the rule rather than the exception, research has been devoted to demonstrating the effectiveness of rehabilitation over spontaneous recovery. Meta-analyses show that stroke rehabilitation programs may improve the functional performance of stroke patients (Ottenbacher & Jennall, 1993). The extent of improvement appears to be related to the timely initiation of treatment, but not to the duration of intervention. Improvements are also associated with the patient's age, older patients taking longer to recover from stroke (Falconer, Naughton, Strasser, & Sinacore, 1994; Kalra, 1994). Regarding the institutional setting of stroke rehabilitation, it seems that early care in specialized stroke units might be most effective (Jørgensen et al., 1995; Kaste, Palomaki, & Sarna, 1995). In the further rehabilitation process, day hospitals may be more effective (and also economically advantageous) compared to conventional hospital management (Gladman, Forster, & Young, 1995; Hui, Lum, Woo, Or, & Kay, 1995).

The 1980s and 1990s have seen the establishment of special stroke units within hospitals. What is needed now are efforts for continuing rehabilitative efforts in the community, cooperation between professions, and better gerontological and geriatric education for professionals working in stroke rehabilitation. In particular, clinical psychologists working in geriatrics commonly report scarce academic preparation and training experiences and relate continuing education to higher satisfaction with geriatric work experiences (Lichtenberg & Rosenthal, 1994). The rehabilitation of a patient who has suffered a stroke is a challenge for the geriatric rehabilitation team and requires diagnostic, management, and counseling resources. Since so many psychomotor functions and psychosocial aspects are affected by a stroke, it can be taken as a general model for rehabilitation in old age. Although the medical treatment of risk factors for stroke (especially hypertension) has proven itself to be an effective prevention, stroke rehabilitation will continue to be an important part of geriatric medicine.

7.23.4.2 Arthritis Patients

The most common chronic condition in old age results from arthritis and rheumatism (US Department of Health and Human Services, 1992). Rheumatoid diseases are characterized by chronic inflammation of joints and soft tissues. Degenerative arthritis results from wearing out of joints (e.g., hip, knee) or from degeneration of bones (e.g., osteoporosis). Age at onset has an aggravating effect on disease expression in rheumatoid arthritis (Keitel, 1993). Symptoms of arthritic diseases are pain (like back pain or pain in the affected joints) and decreasing flexibility of the affected joints (e.g., hip, knee, foot, or fingers). Emotional consequences of arthritis can be increased depressive symptoms or dysphoria (Frank et al., 1992). Functional consequences of arthritic conditions are reduced mobility and losses in certain ADL functions (Badley & Tennant, 1993). Treatment of the several forms of rheumatoid and degenerative arthritis involves anti-inflammatory and analgesic drugs, although medical and physical treatment modalities are closely interrelated and should always be considered together (Baum, 1984). Hence, physical therapy and exercise programs are also extremely important. Sometimes surgery might be effective (like artificial hip joints). In some cases, dietary restrictions might be helpful (degenerative arthritis: weight loss; gout: restriction of calories and alcohol; osteoporosis: additional supply of calcium).

7.23.4.2.1 Physical therapy

In patients with degenerative joint disease, physical exercise programs should be used. Exercises to maintain muscle function are as important as exercises to strengthen specific muscle groups around the affected joint. In contrast, in elderly patients with arthritic conditions, it is necessary to control the underlying inflammatory disease before starting with exercise programs (Baum, 1984). Moreover, morning stiffness and afternoon fatigue make it necessary to schedule active therapy between the end of morning stiffness and the onset of fatigue. Exercise programs have been shown to be effective in increasing mobility, endurance, and functional status (Kovar et al., 1992). Also occupational therapy has positive effects on functional status (Helewa et al., 1991). Moreover, physiotherapy also seems to protect bone mass which may have implications for avoiding bone fractures in the long run (Shawe, Hesp, Gumpel, Sambrook, & Reeve, 1993).

7.23.4.2.2 Psychological interventions

Physical exercise programs not only improve physical health but can also improve mood and reduce anxiety and pain (Frobose & Schule, 1992). Hence, it is an important task for gerontopsychologists to strengthen the compliance of elderly arthritic patients with the therapeutic regimen and exercise programs. The perceived benefits of exercise programs can be an important determinant of exercise participation and compliance (Neuberger, Kasal, Smith, Hassanein, & DeViney, 1994). Moreover, certain sociodemographic characteristics (lower income, lower education, and higher chronological age) might lead to underuse of physical or occupational therapy provided by community services (Mayer-Oakes et al., 1992). The particular challenge for geropsychology with respect to arthritic patients lies in the chronic pain which may undermine life quality severely and permanently (Smith, Wallston, & Dwyer, 1995). The stress and coping literature in general, as well the intervention literature in particular, has not put enough emphasis on the question of what it means to age in the face of chronic and uncontrollable pain. Intervention may thus be aimed at direct alteration of the pain (e.g., by using biofeedback procedures) as well as supportive measures that enable the individual to live better with this chronic stressor (e.g., relaxation techniques, client-centered counseling). Controlled studies show that behavior-oriented interventions might influence knowledge about the disease and pain coping strategies, even if health status deteriorates because of the progressive nature of rheumatoid arthritis (Barry, Purser, Hazleman, McLean, & Hazleman, 1994; Kraaimaat, Brons, Geenen, & Bijlsma, 1995; Matussek, 1992; Simeoni, Bauman, Stenmark, & O'Brien, 1995). Since arthritic diseases affect mobility, the body self-image of an elderly person might be threatened. Clinical psychologists might help arthritic patients to cope with these losses (Jordan & Schmidt, 1988; Lehr, Kruse, & Kruse, 1992).

The musculoskeletal diseases account for the most frequent complaints among elderly persons. Since it is rarely possible to provide the patient with complete symptomatic relief, it is necessary to inform them about adequate health habits, concepts of preventive care, the value of physiotherapeutic and occupational exercises, and the gains to be achieved through behavioral and cognitive therapy.

7.23.4.3 Sensory Impaired Elderly

Losses in hearing and vision are very common in old age (Tesch-Römer & Wahl, 1996b). Hearing impairment undermines the elderly person's everyday communication, whereas losses in vision impede orientation within the physical environment. Aural rehabilitation with elderly suffering from hearing impairments includes technological devices like hearing aids and behavioral communication strategies (Kaplan, 1989; McCarthy & Sapp, 1993; Wahl & Tesch-Römer, 1996). Rehabilitation with the visually impaired elderly consists in orientation and mobility training, exercises in activities of daily living, and the use of magnifying optical devices (LaGrow & Blasch, 1992; Wahl & Oswald, 1996; Wahl & Tesch-Römer, 1996).

7.23.4.3.1 Hearing impairment

Hearing impairment is the second most prevalent chronic condition in old age; about 30% of those over 65 are so severely hearing-impaired that they would benefit from a hearing aid (Davis, 1989; US Department of Health and Human Services, 1992). Presbycusis (or hearing loss in old age) is a high-frequency symmetric hearing loss in old age beginning gradually around the fifth decade and leading progressively and irreversibly to moderate and severe losses of hearing capacity in higher ages (Corso, 1981; Fozard, 1990; Kline & Scialfa, 1996; Willott, 1991; Olsho, Harkins, & Lenhardt, 1985). Age effects for auditory and speech processing independent from hearing sensitivity have also been documented (Humes & Christopherson, 1991). Hearing loss in old age can have negative consequences in the areas of communication, social integration, well-being, and cognitive capacity (Marsiske, Delius, Lindenberger, Scherer, & Tesch-Römer, 1996; Rott, Wahl, & Tesch-Römer, 1996; Weinstein & Ventry, 1983).

There is no medical cure for presbycusis. The only way to help elderly hearing-impaired adults is through rehabilitation with hearing aids (Glass, 1986; Stephens & Goldstein, 1983). Hearing aids are small technical devices which amplify environmental sounds. Although there have been advances in hearing aid technology, hearing aids are problematic devices. Four problem areas in the use of hearing aids have been identified. Elderly hearing aid users complain of poor amplification, stigmatization, financial costs, and handling problems (e.g., inserting the hearing aid in the earmold or manipulating small levers; Franks & Beckmann, 1985; May, Upfold, & Battaglia, 1990). Nevertheless, the use of hearing aids reduces the subjective communication problems of elderly persons with hearing impairment (Tesch-Römer, 1997).

Elderly hearing-impaired patients should be supported in several ways (Tesch-Römer & Wahl, 1996a). Patients should be informed carefully about the functioning and handling of technical aids (in addition to hearing aids, a variety of listening devices exists; Kaplan, 1987). Since hearing with hearing aids is a new experience for the impaired person, they should adapt systematically to the hearing aid (e.g., use the hearing aid first in one-to-one communication and only later in group situations with background noise). Moreover, it could be useful to train the hearing impaired elderly in communication strategies and "hearing tactics," such as asking for well-articulated repetitions, occupying acoustically favorable positions, and lip reading (Vognsen, 1976).

7.23.4.3.2 Visual impairment

As is the case with respect to the elderly with hearing impairments, age-related low vision and its rehabilitation has only received due acknowledgment in the 1990s. The empirical work (Wahl, 1997; see also Wahl & Oswald, in press) has shown clearly that visual impairment has negative emotional and behavioral consequences. For example, significantly higher rates of clinically relevant depression and lower subjective well-being have been reported repeatedly (for overview, see Wahl, 1997; see also Horowitz, 1995). It should be mentioned here, however, that the negative impact on emotional adaptation does not substantially correlate with the objective loss in visual capacity. Regarding behavior, there can be no doubt that the visual loss has profound negative consequences with respect to daily living competence and independent functioning. Moreover, the visually impaired elderly are challenged by the fact that at least some of their preferred leisure activities (reading activities in particular) may become very difficult or even impossible without a good rehabilitation program. Finally, visual impairment is a prototypical environment-relevant loss in competence (Wahl, 1994). Thus, age-related loss in vision may be seen as a prototypical case for an ecological approach to geriatric rehabilitation.

The negative impact of significant (and irreversible) vision loss (e.g., caused by macular degeneration or diabetic retinopathia) makes a multidimensional rehabilitation approach necessary. The main goal of rehabilitation is the restoration of reading capability by the appropriate use of technical devices. A whole range of technical tools, from magnifying glasses to computer-based reading devices, exists (see, for example, Tesch-Römer & Wahl, 1996a). The challenge here is not the device itself but the implementation of these devices in the everyday world of the visually impaired elderly. Moreover, good training with a high degree of "ecological validity" is also needed. A second rehabilitation issue is training in orientation and mobility. The challenge with respect to these rehabilitation techniques lies in the fact that elderly persons often have concomitant impairments of a chronic nature, for example, coexisting hearing, motor, or cognitive impairments. A third issue is training in the domain of daily living tasks. In all of these rehabilitation efforts, training must take place within the elderly person's everyday world. Interventions in the environment of visually impaired elderly are frequently supportive and helpful. With respect to the social environment, it is very important to educate social partners to take the disabilities of their relatives and friends seriously while resisting the temptation to be overprotective. With respect to the physical environment, a whole range of alterations has been suggested (e.g., Hiatt, 1987) such as the enhancement of light conditions (without producing too much glare), the use of contrast and color, and the employment of technical innovations such as special telephones or talking appliances for the kitchen.

To conclude this section, the rehabilitative needs of sensory impaired persons have only been articulated in the 1990s. The aim of this section was thus not only to elaborate on the special needs of these groups of elderly (those with impairments in vision and hearing), but also to emphasize that the rehabilitation of these elderly must consist of more than the mere adoption of technical devices. Truly adequate interventions must implement the devices properly and facilitate the elderly person's adaptation to the new technology. And of course, rehabilitation must enable the individual to better cope with the psychosocial losses caused by the sensory impairment (e.g., Tesch-Römer & Nowak, 1995; Wahl & Oswald, 1996).

7.23.4.4 Demented elderly

Dementia is a very serious problem in the elderly, especially in the very old (see Chapter 10, this volume). In the most common form of dementia, Alzheimer's disease, aphasia, agnosia, and apraxia are present in various combinations as well as emotional and personality changes, memory disorders, slowness in rate of information processing, and the incapacity to fulfill daily living activities. It would therefore be reasonable to question the merit of rehabilitation efforts with the demented elderly. However, professionals as well as society as a whole, cannot neglect the burden and challenge of the tremendous and fast growing number of elderly suffering from dementia. Custodial care is obviously not the right answer. The responsibility for this problem should be shared by all and should address the challenge with those rehabilitative tools which promise at least some measure of success. In this context, it may not be wise to talk about "dementia" in general. There are different degrees of severity, and each patient exhibits a unique profiles of competencies; both of these factors crucially affect rehabilitation outcome.

Rehabilitation efforts undoubtedly should include reality orientation programs and training to cope, at least in part, with daily living challenges. Data suggest that rehabilitative work of this kind may be particularly promising when it starts in the early stages of the cognitive decline process. Intervention studies hint that further deterioration can be delayed by early cognitive training intervention (e.g., Oswald et al., 1988). Family members and other caregivers should be part of rehabilitative efforts, too (Pearlin et al., 1996; see also Chapter 22, this volume). Thus, the comprehensive care of the caregivers, as suggested in the literature on caregiver burden, may also be regarded as a very important part of the geriatric rehabilitation system. In a sense, it also serves important preventive purposes. As is known, being a caregiver for a demented individual heightens the risk of suffering from chronic physical or mental conditions in the long run. Finally, the treatment of dementia provides a prototypical example of how, given unchangeable person characteristics, the possibility of altering the physical environment always remains. This is particularly true in institutional settings, but also relevant in private home living. Some persuasive and empirically proven solutions for modifying and adjusting the environment have been suggested in the literature (e.g., Regnier & Pynoos, 1992).

7.23.5 PRACTICAL ISSUES, RESEARCH QUESTIONS, AND ETHICAL PROBLEMS

The last section of this chapter is concerned with some practical, research-oriented, and ethical problems associated with rehabilitation in old age. Practical problems concern the institutional organization of geriatric rehabilitation, the qualification of staff, and the assurance of rehabilitation quality. Research questions concern the effectiveness of interventions and the development and evaluation of innovative rehabilitation concepts. Finally, ethical problems deal for instance with the distribution of scarce resources within the health care system.

7.23.5.1 Practical Issues

Regarding the institutional organization of geriatric rehabilitation, it has been shown that specialized geriatric units or geriatric hospitals are more effective and more cost efficient than general medical wards (Görres, 1992b). An important problem for elderly patients after rehabilitation is returning home and maintaining independent living in the community. It could be helpful to view this problem from the perspective that individuals with disabilities are handicapped more by barriers in the environments than by their specific impairments (DeJong, Batavia, & McKnew, 1992) and that rehabilitative interventions should be realized in conjunction with community-based long-term care (Miller, 1991; see also Chapter 20, this volume). Another important practical problem is quality assurance (Görres, 1994; Meier-Baumgartner et al., 1992). Conceptions of rehabilitation programs might be very different from their practical implementation. Hence, it is necessary to control the quality of rehabilitative interventions. Three aspects of quality in medical care and rehabilitation can be distinguished (Donabedian, 1966): quality of structure, process quality, and outcome quality. Quality of structure concerns characteristics of the institution, the educational profile of staff, and quality of technical equipment. Process quality concerns characteristics of the rehabilitation process (diagnostics, development of rehabilitation goals, implementation of therapy and interventions, documentation of changes, and team communication). Outcome quality concerns the evaluation of changes stemming from rehabilitative efforts (reduced morbidity and mortality, increased functional independence, ability and motivation for independent living, patient satisfaction). Quality of rehabilitation structure and process are necessary conditions for outcome quality; but outcome quality certainly is what counts in evaluating rehabilitation services (Görres, 1992b).

7.23.5.2 Research Questions

For policy planning and program development, it seems necessary to gather epidemiological data on chronic diseases in old age. The lack of adequate epidemiological data might lead to underestimating the need for rehabilitation efforts. A second major research problem concerns the effectiveness of rehabilitation programs (Görres, Tschubar, & Meier-Baumgartner, 1991). Rehabilitation programs should be tested empirically regarding their effectiveness and efficiency by considering a psychosocial view of life quality as well as a cost-benefit ratio. Although it may be ethically questionable to evaluate rehabilitation programs involving experimental and control groups in pre/post-treatment designs, nevertheless controlled studies should be the standard procedure in rehabilitation research (Wottawa & Thierau, 1990). Finally, the development and evaluation of innovative rehabilitation programs is an important research task. It should be emphasized again that not only dramatic diseases (like stroke) should be the focus of future gerontological rehabilitation research. There are a variety of age-related diseases which urgently require rehabilitation (e.g., arthritis, vision problems and blindness, hearing loss).

7.23.5.3 Ethical Problems

There are several ethical issues concerning rehabilitation in old age (e.g., Spicker, Ingman, & Lawson, 1987). Thinking about rehabilitation implies reference to norms (What is the goal of rehabilitation?), making a decision between rehabilitation and care (When does rehabilitation promise progress in the individual?), and weighing individual and social benefits and costs (What are the gains of rehabilitation compared to the costs?). Considering rehabilitation goals, normative standards (e.g., independent living) could come in conflict with individual values (e.g., security and social contact). Hence, in developing rehabilitation goals, individual values should be considered carefully. Second, before an individual rehabilitation process is initiated, a decision has to be made regarding the rehabilitation potential of the particular individual; sometimes this decision concerns the alternatives rehabilitation vs. care. But even in geriatric, long-term care facilities, nursing does not necessarily have to fulfill a primarily custodial function; rather, it could also be performed according to a therapeutic model of rehabilitation (Burgio & Burgio, 1990). However, sometimes the general goal of rehabilitation has to be given up, and a decision to commit to long-term care be made. This decision might also involve considerations of costs and benefits (Brody, 1987; Hausman, 1987). There are individual costs connected with rehabilitation (e.g., time and effort), but these costs might be outweighed by the potential benefits of rehabilitation outcomes. Additionally, there are also material costs (e.g., financial support for rehabilitation programs). It should be emphasized, though, that rehabilitation is based on humanistic values. This basic ethical orientation stresses that the disabled elderly deserve, as much as anyone else, the opportunity to participate in all aspects of life (Kemp, 1985). Beyond humanistic arguments, however, one might add that current economic conditions make rehabilitation more efficient in the long run than long-term care.

Rehabilitation in old age is a promising field. Empirical research demonstrates the effectiveness of psychosocial interventions in a variety of chronic diseases. Moreover, rehabilitation in old age should not necessarily be dominated by the medical profession. Instead, clinical psychology should demonstrate its rich reservoir of intervention and therapeutic strategies, and clinical psychologists might more often lay hold of the leadership in interdisciplinary rehabilitation teams. Despite unsolved practical issues, open research questions, and difficult ethical problems, rehabilitation in old age is a gratifying field of expertise for clinical psychologists.

7.23.6 SUMMARY

In this chapter, general principles and geropsychological essentials of rehabilitation in old age are reviewed from a geropsychological perspective. Rehabilitation aims at reducing the disability and handicap experienced as a result of disease and impairment. Since aging is associated with increased chronic illness, the goal of rehabilitation in old age is not necessarily complete cure of disease but improving functional capability and maximizing wellness. An overview concerning psychosocial issues and strategies of rehabilitation in old is given, including comprehensive geriatric and psychosocial assessment, restoration of functional independence, cognitive and reality orientation training, therapeutic intervention, motivational and compliance problems, the role of social support, and the ecology of aging. Since different geriatric client groups have different rehabilitation needs, four highly prevalent and serious chronic conditions in old age are treated specifically, that is, stroke, arthritis, sensory impairment, and dementia. The chapter closes with perspectives for psychologists working in rehabilitative settings discussing practical issues, research questions, and ethical considerations.

7.24.1 INTRODUCTION

> As a mental health practitioner, you often receive referrals for the evaluation and treatment of patients who attend a variety of specialty clinics at your medical center. Your most recent referral is to assess and treat Sam P., a 76 year-old man exhibiting symptoms of depression. The Medical Resident treating Sam's cardiovascular disease and arthritis in the hospital's Geriatric clinic had become alarmed and made the referral after Sam began to cry and then refused to answer questions during his most recent medical appointment.

Your clinical decisions regarding the assessment and treatment of Sam P. will be influenced by your model of depression and how it is treated in older adults. Sam's response to treatment, however, will also depend upon your ability to work effectively with professionals from a variety of disciplines who are involved in his care. What difference in your work would there be if you were an official member of the interdisciplinary geriatric clinic team, as opposed to operating separately as a referral service? Few of us have received formal training in the advantages and tasks involved in working in interdisciplinary team settings. This chapter is designed to introduce both the conceptual and practical issues that are a part of interdisciplinary team work.

7.24.2 WHY TEAMS?

Geriatric patients are characterized by two pervasive qualities: their problems are complex and chronic (Binstock & George, 1990; Birren & Schaie, 1990; Dornbrand, Hoole, & Pickard, 1992; Schneider & Rowe, 1990). Problem complexity has many dimensions, including the following: patients may have multiple problems, each exacerbating the others; problems may present differently in geriatric patients than in younger patients; geriatric patients are likely to present inconsistent information about their health concerns; current problems are influenced in complex ways by a lengthy history of medical and/or psychosocial problems; and patients bring complex attitudes towards health care based on their past involvement with other health care providers (Hickey & Rakowski, 1981). Chronic health problems, such as cardiovascular complaints, arthritis, or pulmonary decline, are more typical of older individuals than younger ones (Federal Council on Aging, 1981). While older patients can, of course, also present with acute problems, the typical health care visit is more likely to be prompted by chronic concerns among elders (Woolf, Kamerow, Lawrence, Medalie, & Estes, 1990; Zawadski & Eng, 1988).

Older patients are also more heterogeneous than younger patients. While age typically brings decline, as measured by average capacity, on many biological functions (e.g., visual acuity, cardiac efficiency, speed of male erection, lung capacity), age is also typically characterized by increased variability (Fries & Crapo, 1981). Looking within a group of older adults, the range of capacities will be highly variable for any function, with some individuals displaying better function than the average younger person, whereas others display severe decline. There is also variability within individuals, with some functions remaining at high levels and others showing decline of varying degrees.

Because of these issues, the model of patient care which is the best fit for the management of such patients (i.e., those with chronic, complex problems which present in diverse ways and where stereotyped expectations about patients are inappropriate) is the interdisciplinary team model. This chapter will review basic aspects of interdisciplinary team theory, the natural history of team development, skills necessary for interdisciplinary teamwork, strategies for interdisciplinary team treatment planning, and models of effective interdisciplinary teams.

There has been a growing international awareness of the role of interdisciplinary care in a variety of settings. In Europe, concerns about the care of cancer patients led the Council of Europe in 1987 to create a Select Committee of experts to consider coordination of care for patients. The Committee recommended "the provision of joint professional education as a means of improving teamwork in cancer care ..." (Jones, 1992). The European Health Committee has funded a review of interdisciplinary training of health care staff in member states, and the World Health Organization has supported the development of a network for interprofessional education, based in Linkoping, Sweden (Goble, 1994). In the USA, a network of geriatric education centers (GECs) has been created to provide didactic and clinical training to a wide range of health professionals. These GECs are sponsored by the Bureau of Health Professions of the US Health Resources and Services Administration. Also in the US, the Interdisciplinary Team Training Program (ITTP) is funded by the Division of Veterans Affairs in 12 medical centers to promote direct service and training in a variety of inpatient and outpatient settings.

7.24.3 INTERDISCIPLINARY TEAM THEORY

To say that a group of health care providers is a "team" says very little, as there are many different kinds of teams, organized in different ways to perform different functions. A group that is a team shares a common workplace and set of patients, but teams differ among themselves in their membership composition, commitment to common goals, degree of collaboration in accomplishing team-related tasks, handling of leadership, and the kind of attention paid to team processes. While these factors theoretically could be combined in a large number of ways, in practice the five kinds of teams shown in Table 1 are commonly identified (Takamura; 1985; Takamura, Bermost, & Stringfellow, 1979). Interdisciplinary teams will be described in some detail, along with briefer descriptions of the other kinds of health care team organization.

7.24.3.1 Types of Teams

Unidisciplinary teams (from the Latin "uni," or one) are made up of many providers from a single background, such as a group of public health nurses providing home care. All team members share the same professional skills and training, speak a common language of health care, and function in the same role within the group.

Intradisciplinary teams (from the Latin "intra," or within) are also composed of professionals from one discipline, but include team members from different levels of training and skills within the discipline. For example, a geriatric mental health outpatient clinic team might be composed of a Licensed Psychologist, a postintern, prelicensing psychological assistant, a psychological technician, and two psychology practicum students.

The term *Multidisciplinary team* is often used as if it were synonymous with *interdisciplinary team*, but the two are actually different in very important ways. A multidisciplinary team (from the Latin "multi," or many) is composed of members from more than one discipline, so that the team can offer a greater breadth of services to patients. However, in a multidisciplinary team, each discipline does its own assessment, generates its own treatment plan, implements the plan, evaluates progress, and refines the plan based on their own evaluation (see Figure 1). Team members share information with each other, typically at meetings attended by all team members. There is no attempt to generate or implement a common plan, although members may choose to utilize information obtained in the meeting to revise their own goals or intervention strategies. Multidisciplinary teams are hierarchically organized, that is, there is a designated program "Chief," who is usually the highest ranking professional (commonly an MD). The designated leader is responsible for overseeing the program, leading meetings, resolving conflicts, allocating case load, and so on. Other team members feel responsible only for the clinical work of their discipline, and need not share a sense of responsibility for program function and team effectiveness.

Interdisciplinary teams (from the Latin "inter," or among) also are composed of members from more than one discipline, making a breadth of resources available to patients. Interdisciplinary teams work much more collaboratively, however, as shown in Figure 2. Individual team members do their own assessment, but generally have worked out overall assessment strategies so that patients are not asked redundant questions or submitted to

Table 1 Types of health care teams.

Type of team	*Defining characteristics*
Unidisciplinary team	Members from a single discipline; all members have the same role
Intradisciplinary team	Members from a single discipline, but at different levels of training; roles and responsibilities assigned by training level
Multidisciplinary team	Members from different disciplines; team members have independent roles and meet to share information
Interdisciplinary team	Members from different disciplines; team members have interdependent, collaborative roles and meet to plan treatment and evaluate response
Transdisciplinary team	Members from different disciplines, but team members largely have similar roles and responsibilities

repeated tests. Assessment information is shared with the team as a whole to generate an overall conceptualization of the relationships among biological, psychological, and social aspects of the case (the "biopsychosocial" model). This model is used to generate shared team goals for overall outcomes and to delineate how different disciplines will work together to create desired outcomes. Team members then can implement interventions, either individually or collaboratively as necessary, and evaluate progress. Those evaluations become new assessment data, which are brought back to the team to revise the team's goals and/or strategies for reaching them. This process is repeated as often as necessary until goals are achieved and the patient can either be discharged or a maintenance plan can be put in place.

In an interdisciplinary team, the group as a whole takes responsibility for program effectiveness and team function. Leadership functions are shared among members, with the expectation that everyone must be equally committed to both the clinical content of the program and the process in which team members work together. All team members are assumed to be colleagues, and there is no hierarchical team organization. One member may be designated team "coordinator," but this is understood to be an administrative role and does not imply that the team member has higher status, a stronger say in resolving conflict, or the ability to make unilateral decisions. Because interdisciplinary teamwork requires so much collaboration and consensus decision-making, team members must have a high degree of interpersonal skill. The team must make a commitment to spending time developing effective working strategies and to attending consistently to the process of working together as well as to the quality of the outcomes of their work. Communication skills, role development, leadership skills, conflict resolution skills, and skills for comprehensive conceptualization of cases are necessary for all team members.

This approach has also been labeled "interprofessional care," especially in Europe. A new journal which is rapidly becoming a primary source of articles on interdisciplinary care is titled the *Journal of Interprofessional Care*. Interdisciplinary and interprofessional seem to be interchangeable terms; there do not seem to

be important conceptual distinctions between them.

In *transdisciplinary teams* (from the Latin "trans," or beyond), disciplinary lines are blurred, and team members share role functions to a high degree. For example, nurses, psychologists, social workers, and occupational therapists in an adult day health care program might all drive the van to bring in patients, run groups, see individual cases for supportive counseling, supervise lunchtime interactions, work with patients on increasing physical and cognitive activity, and so on. This model does not have wide application in geriatric settings, since patients generally need the special skills of each discipline, obtained through extensive specialized training, not just generic skills that many disciplines might share.

7.24.3.2 Advantages of Interdisciplinary Teams

The major reason to adopt a particular model of health care is that it provides the most cost-effective results. In cost-effectiveness analyses, effectiveness should be considered first: for example, does the approach reduce symptoms, increase quality of life, promote health, and prevent future illness? If more than one approach is effective, then it is meaningful to ask what the relative costs of each approach are and to select the program that provides the greatest effectiveness for the least cost. Well-functioning interdisciplinary teams provide cost-effective care by increasing the effectiveness of outcomes, thereby decreasing costs for continued treatment (e.g., Hendriksen, Lund, & Stromgard, 1984). There are four usual ways in which this occurs. First, interdisciplinary teams reduce duplication of services, compared to multidisciplinary teams, because team members plan carefully how to allocate resources and to cover necessary tasks. This may involve the collaboration of more than one discipline but precludes duplication. For example, on a multidisciplinary team both the social worker and the psychologist might begin individual psychotherapy for depression with a patient; this would not happen on an interdisciplinary team. Second, a related cost-saving impact is that problems do not fall through the cracks when care is organized by an interdisciplinary team. It is not uncommon on units staffed by multidisciplinary teams for discharge to be planned and then delayed repeatedly as the staff discover that not all the necessary work has been done; for example, the home care coverage is arranged before the physical therapist has become aware of the need to see the patient, and then home care plans have to be rearranged. A third advantage is that interdisciplinary teams can generate more creative interventions, since the ideas and knowledge of a group can be brought to bear and team members can stimulate each other's ideas. Finally, interdisciplinary teams can reduce institutional costs, because they increase staff morale and reduce staff turnover (Lichtenberg, Strzepek, & Zeiss, 1990; Sbordone & Sherman, 1983). As a result, more continuous care can be provided and the cost of recruiting and training replacement staff is reduced.

While there is a need for more research to examine each of the elements of this argument in favor of the cost-effectiveness of teams, the evidence available does support the interdisciplinary team approach. For example, Zeiss & Okarma (1985) compared interdisciplinary team approaches to multidisciplinary care in an outpatient rheumatology clinic setting. Interdisciplinary team approaches were shown to improve patient outcomes on measures of quality of life (such as life satisfaction, self-rated pain, and depression) and measures of health care utilization (e.g., inpatient stays, the most costly care delivery modality). Another study in Sweden compared the outcomes of two groups of female outpatients with rheumatoid arthritis; one group had interdisciplinary care and the other standard care by a rheumatologist. While there were no significant differences in joint function or disease activity, overall health improved significantly over one year only in the interdisciplinary group (Ahlmen, Sullivan, & Bjelle, 1988). Other research showing the effectiveness and/or cost-effectiveness of interdisciplinary teams is reviewed in Lichtenberg (1994) and West and Poulton (1997).

Concern is sometimes expressed that interdisciplinary teams may be too costly, because of the number of disciplines involved. However, interdisciplinary teams have no specific complement of personnel; it is not necessary that every team have a physician, nurse, psychologist, social worker, pharmacist, occupational therapist, and so on. Teams need to include members of those professions who are essential to provide effective care for the identified patient population. Thus, a well-designed interdisciplinary team involves no more personnel than would normally staff a clinic or inpatient unit for that population. The staff are simply organized differently than they would be if the unit had some other type of team (or no team framework at all).

7.24.3.3 Disadvantages of Interdisciplinary Teams (and Ways to Deal With Them)

Even though interdisciplinary teams can be effective, they are not necessarily the treatment of choice in all care settings. Settings where patients have simple, routine problems would probably benefit more from some other form of care, since in-depth discussion of each case is unnecessary if everyone is going to receive essentially the same straightforward intervention. A clinic offering acute care to generally healthy adults, for example, is best staffed by nurses working with physicians; adding staff and meetings for the majority of the presenting concerns would serve no useful purpose. If a 40-year-old woman comes down with bronchitis, adding collaborative care from a social worker, pharmacist, psychologist, and other disciplines to a routine medical visit is unlikely to be cost-effective or satisfying to either the patient or the providers. It is rare, however, that elderly individuals have straightforward problems or benefit from routinized care. If an 80-year-old woman comes down with bronchitis, it may be essential to know that she is caregiver for a demented husband, what other medications she is taking, what her immune status is, and other issues pertinent to her physical and emotional well-being. Social work, pharmacy, psychology, psychiatry, and/or other team members may be essential in planning not only acute treatment for her bronchitis but also backup care for her demented husband.

The other potential drawback of interdisciplinary teams is that they are not organized to provide rapid response in crisis situations; they are organized to provide care for chronic, complex problems. If a patient calls with an acute problem on Tuesday morning, and the next team meeting is not scheduled until the following Monday afternoon, there must be a way for individual team members, or a smaller set of team members, to make emergency decisions. Interdisciplinary teams can handle this by allocating such authority to team members, with the understanding that the issues will be raised at the next team meeting so that the implications of the crisis can be factored into the team's overall plan and the treatment responsibilities of other team members.

7.24.4 NATURAL HISTORY OF TEAM DEVELOPMENT

Groups do not immediately become well-functioning interdisciplinary teams by deciding to make a commitment to that model of care. Much learning and development within the team must occur, over a period of time which lasts at least several months and sometimes longer. The term "team building" is sometimes used to describe activities during this period, but it is a particularly inappropriate term, because of the implications of the word "building," which could imply that a solid structure, impervious to change, is being built. In fact, good teams learn to change continually and to respond fluidly to new demands, new patients, new staff, new health care policies, and so on, through a coordinated, collaborative process. Thus, the term "team development" is preferable, since it implies an ongoing, fluid process.

7.24.4.1 Processes of Team Development

The sequence of experiences that groups go through in the process of developing cohesion and a high level of function has been described by many authors (e.g., Center for Interdisciplinary Education in Allied Health, 1980; Gersick, 1989; Scholtes, 1988), but most influentially by Tuckman (1965). He identified four processes which usually occur in sequence in the process of team development. He labeled these four processes Forming, Storming, Norming, and Performing; they will be described in more detail. It is important to note that these are processes, not stages. If these four processes are seen as four stages that all teams must go through, the opportunity to understand each team's unique pattern can be obscured. In addition, since these are fluid processes, it is not helpful to think of the team as being in only one stage at any given time. For example, a team may be still Storming with regard to some issues while it has already progressed to Performing in other areas. Furthermore, teams can change by leaping forward or falling back in response to personnel changes, the development of new treatment options, stresses or positive events in team members' lives, or a variety of other events. Nonetheless, these processes can be examined to help in conceptualizing the changes and skills necessary for effective team functioning without falling into a rigid stage theory framework.

7.24.4.1.1 Forming

Teams may be formed when programs develop, expand, or are consolidated. A new team must deal with a number of issues, including which staff are part of the team; which patients will be served; what resources are available, such as hospital beds or outpatient visit rooms; how the team treatment planning process will be organized; and so on. Early in the life of the team, these decisions about content matters take priority, and little attention is paid to the process of working together. Team members typically feel a bit awkward with each other, and are willing to develop team relationships but unsure of what that involves. Team members may have concerns about trust, wondering whether it is all right, for example, to express disagreement or concern about how the group is working together.

7.24.4.1.2 Storming

As the team continues to work together, process issues become unavoidable. It becomes clear that team members do not always agree about content issues, for example, how the team treatment planning should be set up. Differences in personal style may need to be faced: one person may handle concerns directly in ways that others see as too brusque, or a team member may try so hard to be tactful that no one can tell what he or she is saying. Team members may make different assumptions about basic working structure, for example, some may assume that starting the meeting at 10 a.m. means 10 on the dot, whereas others assume it means any time before 10.15 a.m. More substantive issues may arise, for example, different beliefs about whether the first-level intervention for depression should be antidepressant medication or psychotherapy. The group will have to learn to voice disagreement in a way that communicates a desire to stay engaged and work out the issues fairly in a collaborative process. If it cannot, the group will likely disband or fall back to multidisciplinary functioning, where individuals can make autonomous decisions without the need for collaboration and consensus.

7.24.4.1.3 Norming

If the group can work on areas of disagreement constructively, a working strategy will evolve. This strategy can be thought of as "ground rules" or norms which describe the way the group will work together and resolve conflict. Norms can be very specific (e.g., "starting at 10 a.m. means any time before 10.05 a.m.") or more general (e.g., "When team members disagree we will engage in a complex process to show our respect and trust for each other and remind each other that good people can disagree; then we will start to work on the substance of the issue"). If the norms developed are reasonable and effective, the group will set aside time to check on its progress (often referred to as "process time") and to continue clarifying its norms. In addition, content decisions will be made and acted on, and the group will begin to feel cohesive.

If the norms are ineffective, the group will feel stuck and rising frustration will throw the group back into Storming. For example, if the team develops a norm that polite agreement will be voiced on most occasions when disagreement occurs, team meetings may seem peaceful at first, but team members who disagree privately are likely to implement their own ideas rather than the ideas ostensibly agreed on in the meeting. This leads to hard feelings and the belief that meetings waste time; the group will have to learn to express disagreement openly and honestly before effective norms can be established that really resolve issues from the Storming process.

7.24.4.1.4 Performing

Over time, the group will develop a high level of effectiveness, called "performing," in which the team becomes expert at using its process to make decisions and get work done. Ground rules will rarely need to be explicitly stated; the group might seem to be on automatic pilot, especially to outsiders who see a seamless performance with deceptively little effort being needed to make complex decisions. The group will feel cohesive and morale will be high.

7.24.4.1.5 Team evolution

Unfortunately, maintaining function in Performing mode consistently over time is unlikely and not a realistic team goal. Key staff members leave; a needed new discipline is added to the team; the program is moved to a different building; or trainees rotate through at four-month intervals. The group must be able to change accordingly, and it is likely that the team must go back through the four processes of team development before settling into Performing mode again. The new team and its resources and responsibilities must be examined in a Forming phase. Old norms may no longer work (e.g., if the team member whose role it was to draw out quieter team members has left), so there will be a Storming process as the implications of change for the day-to-day life of the team become clear. The team will develop new norms, which maintain as much of what worked before as possible, but which also enthusiastically embrace the different skills and personal style of any new team members. If continual change is a reality, for example, if new trainees appear at frequent intervals, the team will develop metanorms for how to allow trainees to have some impact on the group, without constantly having to redefine the group from scratch.

7.24.4.2 Dilemmas of Team Work

One helpful way to think about the processes groups need to go through to become performing teams is summarized in Table 2. Groups must learn to deal effectively with three inevitable challenges: interdependence, complexity, and disagreement.

The first issue the team faces is interdependence; by definition, an interdisciplinary team seeks to share responsibility for patients by working collaboratively. Early in the life of the team, this usually leads to turf battles, as each team member realizes that his or her skills overlap, often substantially, with the skills of other team members. In well-functioning teams, this will be a source of camaraderie and confidence, but early in the team's development, members can fight over who "should" be doing various activities. For example, teams might argue about whether social work or psychology "should" do family therapy, or whether pharmacy or nursing "should" do home visits to check patients' medicine cabinets and prevent mistakes in the home drug regimen. In the Storming process, these issues will be highlighted in order to develop team-specific agreements (norms) about how such tasks will be distributed and/or shared. The section on team role maps below (7.24.5.3) gives more detail on this process.

The second issue is complexity. By definition, interdisciplinary teams are established to deal with complexity, and case discussions, to be useful, must increase the complexity of the

Table 2 Dilemmas of teamwork.

Theme	*Problem*	*Opportunity*	*Work to be done*
Interdependence	Turf battles	Collaboration	Knowledge of and respect for diversity and shared abilities
Complexity	Endless assessment	Comprehensive care	Conceptualization, key issues, language of function
Disagreement	Destructive conflict	Integration of multiple perspectives	Communication skills

whole group's understanding of the interrelationships of each patient's biological, functional, social, and psychological problems. On a well-functioning team, this leads to a breadth of understanding that allows effective comprehensive care. Early in the life of the team, it can lead to information overload and frustration that cases are discussed seemingly without end. In the Storming process, the team must develop strategies for integrating information and capturing the team's complex understanding of the patient in a written format that facilitates treatment planning and implementation. Section 7.24.6 provides some examples of formats teams can use for developing treatment plans that capture complexity and promote collaborative intervention.

The third issue is disagreement. Interdisciplinary teams rely on healthy conflict, in which the different perspectives and knowledge of team members can be presented. It is illusory to believe that these different perspectives will always be complementary; sometimes they are in direct contradiction. For example, the patient may have told one team member that he is sleeping better since starting a behavioral sleep hygiene program, but told another team member that his sleep problems are unchanged. Teams that are having problems are likely to treat these differences as issues in which one team member is right and the other is wrong, leading to conflict destructive to team cohesion and effective patient care. However, in a functioning team, the team members will recognize that there is direct conflict and see it as an opportunity to learn something more about the patient and themselves. The patient may be trying to manipulate one team member to obtain pain medications. Or the patient may be more demented than the team realized and generating unreliable answers to questions. It is also possible that different team members have different interview styles that elicit different information from the patient, or team members may attend selectively to different kinds of information patients present. The important point to remember is that the ability to consider multiple possibilities and integrate multiple perspectives in handling conflict is the hallmark of a highly functioning team. A detailed analysis of strategies for learning to handle conflict effectively are beyond the scope of this chapter, but important sources giving such analysis are presented in Section 7.24.8.

Thus, interdisciplinary teams must develop the capacity not only to deal with the patient issues that the program was originally designed to treat, but also to deal with the interpersonal world of collaborative care. Skills that are necessary for all team members include knowledge and respect for other team members' abilities, the capacity to conceptualize cases holistically, the expertise to develop written team treatment plans which capture the clinical conceptualization, communication skills, leadership skills, conflict resolution skills, and the capability to anticipate and respond to change.

7.24.5 DEVELOPMENT OF INTERDISCIPLINARY TEAM SKILLS

7.24.5.1 Formal Educational Settings

Since the mid-1980s there has been an increase in university-based gerontology programs. However, these programs may not result in the development of skills needed for working in interdisciplinary environments. Clark (1993) argues that the basic departmental structure of universities can create problems for maintaining a truly interdisciplinary perspective. Interdisciplinary principles and practice cannot be taught in a classroom with didactic methods over a short period of time. Instead, interdisciplinary experiences must be integrated into the program at a variety of points, so that students can master the conceptual frameworks and acknowledge the differing value orientations of different disciplines. In discussing interdisciplinary education embedded in specific university departments, Mitchell (1993) states that exposure to clinical settings is essential for beginning health care students if they are to change their traditional orientation and embrace an interdisciplinary perspective of patient care. For example, only 9% of first-year physiotherapy students acknowledged the importance of being able to communicate with other health professionals (Mitchell, 1993); it appears that these students had already developed specific beliefs about therapeutic practice.

Clark's (1993) guidelines for interdisciplinary education involved the following recommendations for educators who need to: (i) clarify the educational objectives of interdisciplinary programs, (ii) attend to team process issues by including a substantial experiential component, (iii) develop educational methods and materials for communicating across disciplines, (iv) focus on obtaining high-level institutional support for interdisciplinary programs, and (v) recognize that interdisciplinary education represents a true educational revolution.

7.24.5.2 On-the-job Training

The majority of professionals are exposed to interdisciplinary team concepts for the first time when at work. Most interdisciplinary health care teams are not formed with the intent to be time limited, and teams have the additional challenge of continuously changing group membership. Because of these factors, team skills need to be taught on an ongoing basis to individuals with very different beginning skill levels. Drinka (1994) points out that it is often the task of ongoing members to teach new members how to collaborate and assume leadership within the team. This process may be difficult at times, since developing a collaborative set involves integrative problem-solving skills in professionals who may be used to working independently. All team members must feel empowered to participate in conflict resolution. While individual members will have varying degrees of formal power, informal power is also important, particularly for new team members. Informal power can be gained through organizational skills, developing increased knowledge about the other disciplines, demonstrating commitment to the team's mission, and increased tenure (Drinka, 1994). Teams can facilitate this process through inservices and retreats that foster both an increased knowledge of other disciplines and a sense of ownership of the team's mission. Individual members may also protect the rights of new members by drawing them into discussions, for example, by asking their opinion before soliciting the view of established team members. Team members also need to feel comfortable enough with the team to disagree in order to avoid poor decision-making (Heinemann, Farrell, & Schmitt, 1994). In addition to team retreats that provide opportunities for informal social activities, team members can practice brain-storming exercises and rotate the role of "devil's advocate," thus formalizing the importance of alternative views (Heinemann et al., 1994).

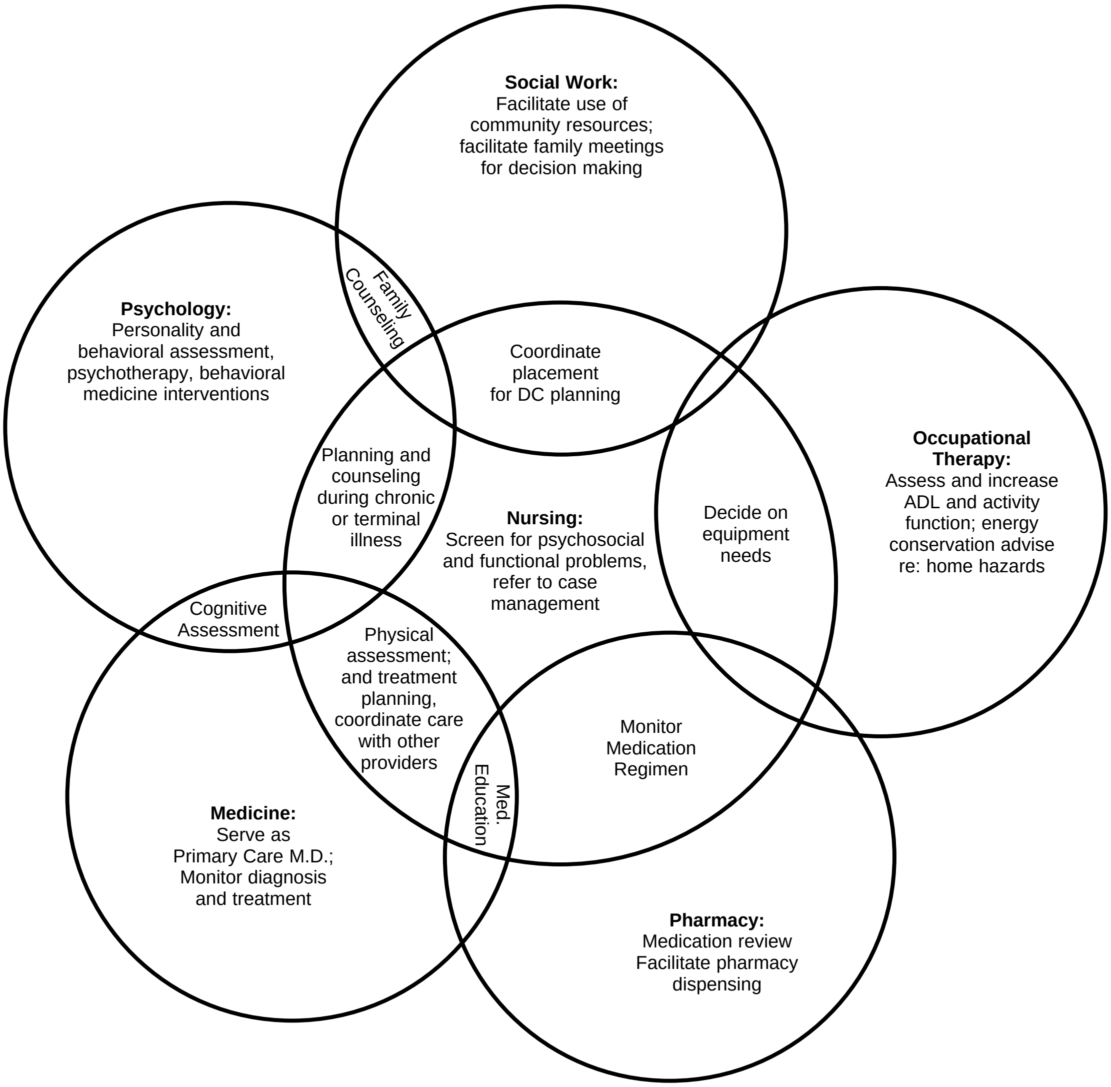
7.24.5.3 Role Definition on Interdisciplinary Teams

One of the activities which helps a team progress is the development of a shared understanding of the roles of each team member. An example of such a role map is shown in Figure 3; this role map is adapted from one generated for a hospital-based home care team (HBHC). This Department of Veterans Affairs program serves home-bound older patients and their caregivers; all team members drive to each patient's home to assess needs and provide services. Team members shown in the figure are a physician, four nurse practitioners, a social worker, an occupational therapist, a pharmacist, and a psychologist. Each discipline is represented by an oval, and each oval overlaps with others. Within each discipline's oval are listed the components of their role. In the part of the oval that does not overlap with other ovals appear clinical responsibilities assumed only by that discipline. In areas where two circles overlap, clinical responsibilities appear which either discipline might perform or which the two team members might perform as co-therapists. For example, either psychology or medicine might do cognitive screening.

There are also areas where three, or even more, ovals overlap. In those intersections appear tasks which several team members might perform, for example, nursing, medicine, or pharmacy might all educate patients about the effects and side effects of medications. Figure 3 has been simplified for clarity and does not include all the roles of any of the disciplines, but a more complex version could be generated that did demonstrate the complete range of tasks performed.

Generating and/or examining such a diagram provides several kinds of information. First, it can delineate all the clinical services which patients could receive from this team. Second, it clarifies for each discipline what they offer to the team and what the team will expect them to provide. Third, it clarifies areas which, on a well-functioning team, will be opportunities for conjoint efforts or, in a poorly-functioning team, will be sources of conflict that can be termed "turf battles." If pharmacy and nursing each want to hold the unique right in this setting to educate the patient about medications, for example, the two disciplines are likely to be in conflict about this issue. If each sees the other as a collaborative resource instead, team work (and patient care) will be enhanced. Fourth, Figure 3 suggests which disciplines may have the most difficulty speaking each other's language. The roles of pharmacy and psychology, for example, overlap very little in this setting. In a well-functioning team, members will see these as complementary functions and take pride in being able to provide a range of services well beyond the purview of any discipline. In a poorly functioning team, members will complain about the time taken to discuss issues outside their own scope of practice and compete for time to discuss the issues most closely connected to their own role.

To generate a role map which captures the realities of a specific program and the disciplines on its team takes some time, but is usually well worth the effort. Each team member needs to specify his/her role and present it for team discussion; often this results in adding tasks to the list which the team member did not specify but recognized when mentioned by other team



Social Work:
Facilitate use of community resources; facilitate family meetings for decision making
Psychology:
Personality and behavioral assessment, psychotherapy, behavioral medicine interventions
Family Counseling
Coordinate placement for DC planning
Occupational Therapy:
Assess and increase ADL and activity function; energy conservation advise re: home hazards
Planning and counseling during chronic or terminal illness
Nursing:
Screen for psychosocial and functional problems, refer to case management
Decide on equipment needs
Cognitive Assessment
Physical assessment; and treatment planning, coordinate care with other providers
Monitor Medication Regimen
Med. Education
Medicine:
Serve as Primary Care M.D.; Monitor diagnosis and treatment
Pharmacy:
Medication review Facilitate pharmacy dispensing

Figure 3 Geriatric interdisciplinary team role map.

members. This also begins to highlight the areas of overlap, as team members recognize some of their own tasks on colleagues' lists. After all disciplines have presented their roles, someone on the team, or a small group, needs to organize the lists to capture graphically areas of overlap and areas of unique function. This document can then become a tool to help in shaping norms and to help in the process of socializing new team members and reaching or returning to the Performing level of team process.

7.24.6 INTERDISCIPLINARY TEAM TREATMENT PLANNING

Interdisciplinary teams generate treatment plans through two interlocking processes. First, the team must be able to conceptualize patients broadly, incorporating all the relevant information and the relationships between different problems. Thus, the team must go beyond simply listing patient concerns on a problem list, to look at the relationships among problems. For example, a patient's depression may be triggered by loss of independence in activities of daily living (ADL) and the depression may be the primary reason (because of the patient's apathy and hopelessness) for medication nonadherence. Psychology or psychiatry could list depression on the problem list; occupational therapy could list difficulties with ADL; pharmacy could list medication nonadherence. But the efforts of each discipline to deal with these problems will be enriched if the linkages among problems are understood.

This type of conceptualization will be demonstrated in more detail in the case study in Section 7.24.7.

Second, the team must have a structured format for guiding and capturing on paper the treatment planning process. That structure should, at minimum, specify which problems will be treated, what the goals of treatment are, what treatment strategies will be used, and which team members will be involved. It is helpful to indicate which team members will be involved by name as well as discipline, to emphasize accountability. The plan may indicate time frames, specifying which interventions should begin immediately, which will be implemented after progress is made on initial problems, and the expected time frame to accomplish the goals. The plan could also include space to update status of progress generally, such as noting if the treatment goals are accomplished

The plan should be available to all team members to guide their activities in implementing their own roles, and it should be available at team meetings to guide discussion. To ensure continuous availability, teams can circulate copies to all members or keep charts in an easily accessible place. To guide team discussions, plans can be shown using overhead transparencies, or circulated at the meeting, or a team member can review highlights of the plan before case discussion.

7.24.7 INTERDISCIPLINARY TEAM CONCEPTS IN ACTION: TEAM RESPONSE TO A GERIATRIC PATIENT WITH MULTIPLE MEDICAL PROBLEMS AND DEPRESSION (SAM P.)

In order to further clarify the use of the team treatment planning process, we return now to the case which opened the chapter, Sam P., a man referred to a mental health practitioner for the assessment and treatment of depression. Let's look at this case in more detail to see how an interdisciplinary perspective influences his treatment. This case also offers the opportunity to contrast how an interdisciplinary team would approach the planning and treatment processes differently from a multidisciplinary team.

> Sam P. is a man in his mid-70s of Italian-American background. He has been married to his wife, Pauline, for 40 years: they have been in the same two-storey home for their entire marriage and enjoy gardening, visiting with family and friends, and participating in some church activities. For the last 15 years, Sam has had progressively greater trouble with day-to-day function as a result of his medical problems. His arthritis results in joint pain, especially in his hands, knees, and hips. This joint pain also negatively affects his sexual function. Sam's cardiovascular disease results in impaired blood flow, especially to his legs, to the extent that he gets cramping pain in his legs after walking as little as half a block. Impaired blood flow also has impaired Sam's ability to get and keep an erection. Taken together, these problems have affected almost every aspect of Sam's life. He has trouble getting up and downstairs in his home, he cannot do the gardening he enjoys, he has trouble joining family and friends on outings, and he and his wife have stopped any form of physical intimacy because of his frustration with his sexual function problems.
>
> Sam is taking various medications for his medical problems and comes to the geriatric clinic every three months on average. At the clinic, the medical residents rotate every four months; Sam feels frustrated when he has to retell information to a new doctor. He sometimes gets disgusted and angry with clinic staff, and forgets the questions he has about his medications. On several occasions, Sam has lost track of his medication schedule, became overmedicated, and developed severe nausea, diarrhea, and cognitive confusion. At other times, he has failed to take medication for days at a time, resulting in increased pain and decreased energy.
>
> Sam says that he sometimes feels depressed and useless. He and his wife used to baby-sit their infant granddaughter, but Sam can no longer keep up with a toddler and gets rattled by too much noise and activity. Sam used to enjoy activities in his neighborhood, such as pot-lucks and reading groups, but has stopped going because of his physical problems. His major independent forms of recreation before his decline were driving his friends on outings and attending Elks Club meetings; he has also stopped trying to do these things. He reports that he is often "blue" and tearful, and describes a poor appetite and waking early, about 4 a.m., several days a week.
>
> During the 40 years of their marriage, Sam and Pauline enjoyed physical intimacy and Sam describes feeling sad and frustrated that he "can't perform." Besides problems with erections, Sam often feels tired and is afraid that having intercourse would put too much physical stress on his joints. Sam also admits to feeling self-conscious about the way he looks and has a hard time believing that his wife still finds him sexually attractive.

You can see from this case description that a competent professional in any one discipline cannot address the many issues involved in Sam's physical and mental health. Like many older adults, his treatment should involve the cooperation of a number of disciplines, including nursing, social work, medicine, psychiatry, pharmacy, occupational therapy, and psychology. The psychologist involved in the case would probably conduct a careful mood assessment, then contact the psychiatry consult service to determine if Sam's medication regimen is commonly associated with depression. Several key issues likely to be related to Sam's negative mood would be examined: decreased participation in activities that are both meaningful and pleasurable for him; beliefs that he is no longer useful to others; and disruption of his marital intimacy, both physically and emotionally, as a result of his sexual dysfunction. The psychologist may consider some neuropsychological assessment to evaluate Sam's short-term memory, given that he has forgotten to take some doses of medication in the past and taken too much medicine at other times. There are additional areas that could be targeted for change, such as his frustration and communication difficulties with clinic staff. Psychiatry and psychology may discuss together the usefulness of prescribing antidepressant medications.

The other disciplines involved in his care would have their own concerns and areas of interest. The geriatric medical resident assigned to Sam would continue to evaluate choice of medications with the goals of reducing pain and minimizing joint damage, and maximizing cardiac function and circulation. The nursing staff may want to further educate Sam and his family about his medical diagnoses and the reasons for daily fluctuations in pain and function. Occupational therapy might work with Sam on selecting assistive devices to aid him in difficult tasks (e.g., buttons, zippers, jar lids), create hand splints to protect his hands from further arthritic damage, and plan ways for him to continue important daily activities (e.g., design a table-top garden for which he does not have to kneel). The social worker involved in the case would be aware that Sam and Pauline's two-storey house is a problem because of Sam's swollen knees and peripheral neuropathy, and would discuss housing and long-term plans with them. Sam's episodes of overdosing on medications would be concerning to the pharmacist, who may consider ways to reduce the likelihood of this re-occurring.

So far, it may appear that each professional could execute her or his own treatment plans without the input of the other disciplines (i.e., as a multidisciplinary team). Upon closer inspection, the evaluation and treatment goals in each area overlap in a way that creates the potential for conflict as well as cooperation. For example, the psychologist's suggestions for increasing pleasant activities may appear to directly contradict what Sam has been told by the occupational therapist and the geriatric medical resident. In addition, the psychologist and social worker might be convinced that his medication overdose and seeming confusion during appointments are related to complex issues such as anxiety about his illness, some recent decline in short-term memory that should be monitored, his response to the staffing patterns of the clinic, and a lack of support from his family. This may contradict the pharmacist's approach that the main issue is regulating medication regimens and providing more education about the purpose of each medication. From a different perspective, the medical resident may believe that too much time is spent in team meetings discussing Sam's emotional and psychosocial reactions to his illness. After all, the severity of his symptoms would decline significantly if he would just carefully follow his medication regimen and not engage in strenuous physical activity. These conflicts might be traced to several aspects of the team setting: poor patterns of communication during and outside of team meetings, a decision-making process that minimizes opportunities for discussion or dissent, and a lack of understanding and respect for each discipline's norms and perspectives for patient care.

In contrast to how a multidisciplinary team would approach the patient, the interdisciplinary team in this case would spend more time and attention coordinating Sam's evaluation and care. Through regularly scheduled opportunities for education during team meetings, the interdisciplinary team members would develop a greater understanding of the competencies and perspectives of the other disciplines. This would result in the team's enhanced ability to identify shared treatment goals and the specific needs for collaboration necessitated by each patient.

What team response could be expected in Sam's case? The following section describes an interdisciplinary effort focused on several interwoven goals and strategies. From the information provided in the case description plus some additional assessments, a treatment plan was developed. An important issue that became clear during interdisciplinary discussion was that Sam's care had been fragmented and spread across several specialty clinics, rather than being consolidated in a primary care setting and coordinated. Sam's loss of mobility was a particular focus. He had been seen by orthopedics, who planned hip replacement surgery with the expectation that he would be able to return to most of his prior activities after surgery. However, when seen by cardiology, he was told that hip replacement surgery was unnecessary and that he would be more mobile if his cramping pain (known as claudication) was treated with a medication to improve cardiovascular performance. Sam tried that medication, but stopped using it because of side effects, especially headaches. When he stopped using it, he did not go back to cardiology to try another medication, nor did he go back to orthopedics, because of his pain, difficulty getting to the doctor for appointments, and his general discouragement and depression. Thus, his treatment plan was based on the idea that his care needed to be coordinated, not fragmented, and that regaining mobility would be key to resolving many of the other issues that Sam presented. The three interwoven issues that were targeted as initial goals thus became: (i) decrease depression; (ii) reduce joint pain; and (iii) improve cardiovascular performance. It was expected that improvements in these three areas would result in improved function across a variety of activities, including increased mobility, return to valued social and recreational activities, and improved sexual function with his wife. These functional changes were also considered important aspects of the treatment plan, and are woven into it. The frst two elements of the treatment plan are shown in more detail in Table 3. This also shows how the goals for the first two problems are related to specific intervention strategies, the disciplines working together to provide services, and the time frame for completing each intervention. The reader will also notice from Table 3 that the suggested interventions were linked closely to a jointly developed conceptualization of each problem.

After targeting Sam's main problems and agreeing on etiological models for each, the team identified goals that could be linked to time-specific interventions facilitated by team members. The first, central issue was addressing Sam's discouragement about treatment and alienation from health care providers. A plan was developed to provide Sam with more personalized and consistent care by establishing a stable staff person on the interdisciplinary team as his primary contact person. This staff member (the social worker in this case) could help him use his medical appointments more effectively and efficiently and provide support and encouragement to pursue more vigorous treatment of his medical problems. This intervention also improved the team's overall knowledge of Sam's medical and psychosocial status. The team believed that improving Sam's involvement with care and motivation to participate fully in care were crucial in meeting the second goal of reducing joint pain in his hips by rescheduling hip replacement surgery. In turn, reducing that joint pain was essential to work on increasing mobility.

The team viewed Sam's depression as heavily influenced by his progressively decreasing involvement in pleasurable activities due to chronic pain and decreased mobility. The team encouraged Sam to participate in brief psychotherapy with the team psychologist, with the further expectation that the psychologist and Sam would work with the occupational therapist on selecting activities and environments that would match his interests and degree of physical disability. As his physical situation improved, with surgery and medication, the level of activity could increase, but they could also develop strategies for increased pleasure, satisfaction, and sense of competence even before the surgery. This could help combat his discouragement and passive withdrawal from treatment, just as the closer relationship with the team did. Antidepressant medications were not recommended by the psychiatrist because of the strong situational components tied to his recent depression (i.e., decreased involvement in pleasant activities, chronic pain) and Sam's difficulty in managing his other medications.

Sam was initially surprised at the team's feedback that his feelings of depression were important and could be treated. He had expected someone in the clinic to tell him to "not be so emotional and just deal with it." After talking to the psychologist about the team's view of his depression, Sam attended four individual sessions with the psychologist and learned to identify the activities that were most closely linked with feelings of happiness and satisfaction. Sam and the therapists carefully planned ways to retain the daily activities most meaningful to him and to adapt activities, like gardening, that he had believed must be given up. He reported that, while still feeling sad at times, he was less tearful and more energetic. In addition, his appetite and sleep schedule returned to a more normal basis.

The team also arranged an appointment for Sam and his wife to meet with the geriatric medical resident and the psychologist. During this visit, Sam and Pauline were able to discuss their concerns about the impact of Sam's pain and physical functioning on sexual activity. They agreed to try different body positions and touching that resulted in less pressure on his affected joints. Sam also began to use a warm bath and pain medication just prior to making love and reported that this was helpful. After Sam's hip replacement surgery and improved function with cardiovascular treatment, the therapists helped Sam and his wife work out additional positions and timing for sexual activity and to continue communicating clearly

Table 3 Treatment plan for Sam P.

Problem area	*Treatment goal*	*Intervention*	*Disciplines involved*	*Timeframe*
(1) Depression (linked to discouragement about treatment, reduced pleasant activities, and loss of marital and sexual intimacy)	(1) Increase	(1) Offer following therapies:	(1)	(1)
	(i) Understanding of and confidence in treatment providers and potential treatment outcomes	(i) Consolidate care in geriatrics clinic; appoint a long-term staff member to meet with client every visit to assist in clarifying issues and questions for the medical resident; preclinic discussion of case with resident to ensure knowledge of treatment plan and consistent follow-up	(i) Social worker as long term staff contact; entire team involved	(i) Ongoing
	(ii) Pleasant activities	(ii) Brief psychotherapy using OT as consultant on adapting activities	(ii) Psychology and	(ii) 4 months
	(iii) Level of physical intimacy	(iii) Joint appointments with patient and wife for problem-solving re. sexual activity	(iii) Medicine and psychology	(iii) 6 months
(2) Joint pain, particularly in hips, knees, and hands (believed by the team to be primarily a result of osteoarthritis, exacerbated by lack of joint protection activities)	2(i) Decrease pain	2(i)(a) Reschedule hip surgery, with close communication between geriatrics clinic and orthopedics	2(i)(a) Medicine	2(i)(a) 1 month
		(i)(b) Increase consistent use of pain medication through education and increasing motivation	(i)(b) Pharmacy and psychology	(i)(b) 2 months
		(i)(c) Use hand splints to reduce pain and prevent deformity	(i)(c) OT	(i)(c) 2 months
	(ii) Prevent further problems	(ii) Patient and family education about arthritis self-management	(ii) Nursing and psychology	(ii) 3 months
	(iii) Reduce stress on joints in day to day life	(iii) Assist patient and wife make long range plans about housing if still needed after hip surgery; adapt gardening and daily tasks using joint protection techniques and assistive devices	(iii) Social work and OT	(iii) 6 months, if needed

OT, occupational therapy.

about their expectations and occasional problems.

Sam was able to keep better track of his medications through the suggestions and encouragement of the pharmacist and the nurse, especially after his depression began to resolve with treatment. They helped him understand the differences between different medications in his regimen and set up a procedure for organizing his weekly medication regimen. There were no further instances of taking too much medication, and Sam was better able to report to the geriatric resident on whether different medications were having their intended impact.

Ultimately, Sam did have hip replacement surgery, which resulted in a significant improvement in his pain and mobility. During his postsurgery recovery, the work on depression and maintaining a strong team relationship continued, resulting in a rapid recovery and reestablishment of a wide spectrum of activities, including a return to more social contact. After the surgery, Sam was able to stay in his two-storey house, so the social work intervention which was considered was not, in the end, necessary.

7.24.8 RESOURCES AND TRAINING MATERIALS

While the case of Sam P. demonstrated an interdisciplinary team at work in a hospital setting, this type of case formulation and treatment is important when working with older adults in a variety of mental and physical health care settings. This chapter has introduced the concepts and practice of interdisciplinary teamwork, with the expectation that more resources and experience will be needed for those wanting to apply this information to their own work groups. This section discusses additional written materials and training guides that may be useful.

The disciplines of industrial/organizational psychology, social psychology, and business management have traditionally devoted the most attention to studying group behavior, decision-making, and conflict resolution. However, a separate literature on interdisciplinary team functioning in health care settings has also developed. Some basic early work is covered in an annotated bibliography (Czirr & Rappaport, 1984). Early work will be mentioned, but the chapter will emphasize more recent publications and training approaches. While it is beyond the scope of this chapter to review these literatures in depth, the following section outlines several articles and books that provide a context for understanding interdisciplinary team issues.

7.24.8.1 Outcomes and Descriptions of Interdisciplinary Teams

The literature on team functioning in geriatrics is dominated by articles describing and evaluating interdisciplinary programs (e.g., Rubenstein et al., 1984; Zimmer, Eggert, & Schiverton, 1990) and discussing barriers to effective team functioning (e.g., Saltz, 1992; Chafetz, West, & Ebbs, 1988). Qualls and Czirr (1988) discuss how models for professional functioning differ across disciplines and influence team participation and collaboration. Goldstein (1989) looks at team functioning from the perspective of physicians and offers practical advice for developing team approaches in geriatric health care settings. Drinka and Streim (1994) provide case examples of teams functioning ineffectively and suggest intervention strategies to help teams escape from "health care purgatory." In his book *A Guide to Psychological Practice in Geriatric Long-term Care*, Lichtenberg (1994) does an excellent job advocating for an interdisciplinary approach in long-term care settings. The chapter on creating effective interdisciplinary teams is particularly useful for those needing more information on models for training nursing assistants, organizational interventions in long-term care settings, and specific examples of team-development approaches (including the Department of Veterans Affairs' Interdisciplinary Team Training Program). Lichtenberg also reviews the empirical literature on the relationship between team functioning and patient outcome, noting studies such as the work by Feiger and Schmitt (1979) that demonstrate a relationship between collegiality in interdisciplinary health teams and improved physical, social, and emotional functioning in patients.

7.24.8.2 Team Training Guides

There are a variety of "hands-on" training manuals for those interested in practical advice and examples of team development exercises. Some of these guides target work groups in business, while others are specific to health care settings. Several are particularly helpful. While not specific to health care environments, *The Team-Building Sourcebook* (Phillips & Elledge, 1989) is a comprehensive resource for practicing team consultants and others who are involved in team development. This guide discusses the steps of the team development process and provides numerous examples and activities to be used in addressing the specific needs of a given team. A strength of this resource text is the inclusion of agendas and workshop suggestions for a variety of tasks, giving specific amounts of time for team development activities. For example, the implementation section of the source book outlines the possible contents of team development workshops lasting from four hours to two days. Eleven modules are presented with step-by-step instructions for conducting team development sessions, complete with handouts and materials to be used in flip charts.

The Team Handbook: How to Use Teams to Improve Quality (Scholtes, 1988) is another excellent team-training guide. Although it was also developed with business consulting in mind, the handbook is relevant for health-care professionals. This work discusses quality improvement concepts, then shows how productive meetings and cooperative work groups are important components of increasing team efficacy. Scholtes addresses common problems in team settings (e.g., dominating or reluctant participants, feuding team members) and makes specific recommendations on how to work through these difficulties. The handbook also includes an entire chapter of team development activities and exercises, from handling introductions to helping team members make observations about group processes.

A Guide to Team Development was developed by an interdisciplinary team (Center for Interdisciplinary Education in Allied Health, 1980) at The University of Kentucky's Center for Interdisciplinary Education in Allied Health. This field manual was designed for faculties who train students in team development. It identifies tasks and exercises focused on organizing team meetings, goal setting, decision-making, generating an open and creative environment for team problem-solving, and evaluating the team process.

An assessment tool for evaluating interdisciplinary training efforts is The Interdisciplinary Education Perception Scale (IEPS) (Luecht, Madsen, Taugher, & Petterson, 1990). The IEPS is an attitude inventory that assesses perceptions of professionals, and has four factors: beliefs about competence and autonomy; perceived need for cooperation; perceptions of actual cooperation among different disciplines; and understanding others' values.

The Centre for the Advancement of Interprofessional Postgraduate Education has identified interprofessional training initiatives throughout the United Kingdom (CAIPE, 1989). The University of Newcastle Health Care Research Unit also developed a report that suggested practical steps for increasing collaboration among health care professionals. More broadly in Europe, an organization, the European Network for Development of Multiprofessional Education in Health Sciences (EMPE), has been developed to promote interprofessional education (Goble, 1994). This organization offers expert resources and opportunities for meeting to share educational plans, implementation strategies, and data. Resources for promoting interprofessional collaboration have also been developed in Finland (Lamska, Hietanen, & Lamsa, 1994) and Romania (Stephenson & McCreery, 1994).

7.24.8.3 Communication Training

There are occasions when a group has already accomplished many of the tasks needed to function as an interdisciplinary team, yet team members have difficulty resolving conflict or communicating clearly. Two books are recommended that specifically address conflict resolution and communication skills. Gottman, Notarius, Gonso, and Markman's *A Couple's Guide to Communication* (1976) is a classic in the psychotherapy and counseling literature for very good reasons. Although it targets communication difficulties in married couples, this work provides the rationale and description of exercises that can improve communication in a variety of contexts and settings. The first five chapters in the book, covering skills such as listening, validation, constructively expressing grievances, negotiating agreements, and handling hidden agendas, are especially helpful. A highly recommended book by Fisher, Ury, and Patton (1991), *Getting to YES: Negotiating Agreement Without Giving In*, is based on work done by the Harvard Negotiation Project. *Getting to YES* addresses both the conceptual orientation and practical implications of principled negotiation, a method of negotiation that can be used in a wide variety of circumstances. In principled negotiation (also called negotiation on the merits), negotiators are encouraged to separate the people from the problem, focus on interests instead of positions, generate a variety of alternatives before making decisions, and base results on some objective standard. These authors also discuss handling several common dilemmas in negotiations, including negotiating with someone who is more powerful and working with others who continue to rely on positional bargaining or unprincipled tactics.

7.24.8.4 Factors that Influence Team Functioning

Interdisciplinary teams are based on nonhierarchical interactions, but team members come from a larger social structure that often emphasizes rank and status. Work has been done in areas such as the behavior of low-ranking group members, and cultural and gender differences, as they influence the decision-making strategies of groups. Lichtenberg, Strzepek, and Zeiss (1990) discuss factors that limit the participation of psychiatric aides in treatment teams. They use a particular program, the Veterans Administration's Interdisciplinary Team Training in Geriatrics Program (ITTG; now known as the Interdisciplinary Team Training Program or ITTP), as an example of how to bring about change.

Mechanic (1962) discussed the attributes of the social structure of an organization that led to greater power and influence by lower ranking group members. When these concepts are applied to team members from traditionally lower-ranked disciplines (i.e., recreational therapists, nursing assistants, clerks), Mechanic's work has implications for team interventions. For example, teams can increase opportunities for these staff to interact and have access to other professionals, which will increase their influence in teams and improve the quality of team decisions. The team can also develop ways to recognize explicitly that individuals from low-ranking disciplines often have important expert knowledge that is not readily available to others in the team.

On a related topic, Kirchmeyer and Cohen (1992) discuss the concept of constructive conflict and then demonstrate empirically how specific behaviors in multicultural groups may increase the participation of ethnic minorities. This approach is described in more detail by Tjosvold (1991), who presents some actions that can be taken by designated group leaders to encourage the active involvement of all team members. Kelley and Streeter (1992) review issues and research on gender in organizations, covering such wide topics as trends in work patterns and perceived gender differences in performance and job attitudes.

7.24.9 HELPING WITH INTERDISCIPLINARY TEAM DEVELOPMENT

It should be clear that all interdisciplinary teams, no matter how motivated and talented the members, will have difficulty from time to time. The material presented thus far is intended to provide a theoretical background for how teams function, an example of good interdisciplinary team treatment planning, and information on resources where more can be learned about team functioning and essential skills for teamwork. It is also helpful to consider how to try to have a positive impact as a team member or how to help with program development.

First, there is a need to respect a fundamental tenet of interdisciplinary team development: by definition, no single person can make a group become an interdisciplinary team. Even with enthusiasm about interdisciplinary team ideas and a desire to see them put into action, no single person can make this occur, even if he or she has the institutional power to define program goals and organizational structure. Interdisciplinary teams ultimately depend on and are the embodiment of a powerful principle: people support what they help create. A group can only become an interdisciplinary team if the group members decide themselves that they want to take on the responsibilities of shared leadership and interdependent functioning. An individual's role can be one of bringing the concept to the table and trying to generate shared enthusiasm for it, but it cannot be mandated from above. If the group must function in a way mandated by authority, it is, by definition, not an interdisciplinary team.

If the group embraces the interdisciplinary concept, an individual can help create experiences that will move the group forward. It is usually essential early in the life of the team to generate a vision statement that articulates team members' understanding of program goals, including what patients are to be served, what resources are available to serve them, and the expected impact of the program. This can help the team negotiate the Storming process by providing a grounding in a commonly held set of values.

When the team has a shared sense of purpose, other training experiences largely mirror the organization of this chapter. Team members need to learn about interdisciplinary concepts and to confirm their commitment to shared responsibility for the success of the team. They need to recognize how much there is to know, for example, about each others' professions, about sharing leadership, and about communication skills and conflict resolution. The group optimally will decide together on strategies for appropriate additional training. Team members can train each other, or it may be necessary to bring in a team consultant. It will be especially important to bring in a consultant if the team cannot handle successfully the Storming process, either because the group avoids all conflict or because conflict escalates uncontrollably. There are systems level factors that encourage team members to ignore conflict. For example, factors such as low staff-to-patient ratios, lack of proximate office space that would allow informal staff contact, and few direct incentives for team process meetings

(Drinka, 1994) all point to the benefits of having a consultant assist in the process of team development.

In the training process, it is particularly helpful to find a balance between content and process. During process time, team members can share personal reactions to the tensions and pleasures of interdisciplinary work and discuss experiences with communication styles in the group. During content training, it is very helpful to have the group develop its own unique role map. This also provides an opportunity for each discipline to educate the others about its skills, training experiences, licensure status, and model of health care. The group can also look at different approaches to team treatment planning and choose one that best fits the team's mission and style of working.

Any team member can suggest such strategies and contribute to implementing the group's decisions. If the group does not develop effectively, or one individual seems to make all the suggestions or guide all the training experiences, bringing in a team consultant would be a good idea. The more one person tries to carry a reluctant team, the less interdisciplinary it will be, and the more that person will become the *de facto* leader of a multidisciplinary team. In such cases, the most helpful thing to be done is to relinquish power in order to encourage other team members to join in the process of assessing the team's problems and generating solutions.

7.24.10 SUMMARY

Interdisciplinary teams are a particularly appropriate way to organize health care for geriatric patients, who typically have complex, chronic problems. The interdisciplinary team provides care in which several disciplines coordinate assessment and treatment, so that problems can be dealt with consistently and comprehensively. Interdisciplinary teams are characterized by a nonhierarchical organization, in which responsibility for the effective functioning of the team is shared by all team members. This requires that team members be excellent representatives of and advocates for their disciplines. It also requires that team members have training in team theory, leadership skills, and communication skills, including conflict resolution skills. Interdisciplinary teams go through a process of development. Newly formed teams work out goals and basic models of function; this process usually highlights areas of disagreement among team members in strategies of care and/or personal interaction styles. As groups work out these disagreements, they develop shared norms which define the team's working strategies. With experience, most interdisciplinary teams reach a high level of function and deliver cost-effective care while supporting staff morale.

Interdisciplinary teams come about through the efforts of health care providers who are committed to the idea that patients will be best served when their care is coordinated and provided by team members who challenge, learn from, and rely on each other. Interdisciplinary teams depend on the wise and creative integration of diverse viewpoints. Sometimes those are complementary, but sometimes they are conflicting. The team must learn to value diversity, remain cohesive when viewpoints conflict, and negotiate agreement to which all team members are committed.

8.01.1 INTRODUCTION

Interest in health behaviors is derived from two assumptions; that a substantial proportion of the mortality from the leading causes of death is attributable to the behavior of individuals, and that the behavior is modifiable (Stroebe & Stroebe, 1995). It is now widely recognized that individuals can influence their own health and well-being through the adoption of health-enhancing behaviors (e.g., exercise) and the avoidance of health-compromising behaviors (e.g., smoking). The identification of the factors which predict who engages in health behaviors has become a focus of research in health psychology and other health-related disciplines in recent years (e.g., Adler & Matthews, 1994; Conner & Norman, 1996a; Glanz, Lewis & Rimmer, 1990; Hockbaum & Lorig, 1992; Rodin & Salovey, 1989; Winett, 1985).

The health behaviors examined have been many and varied; from health enhancing behaviors such as exercise and healthy eating, on the one hand, to avoidance of health harming behaviors such as smoking and excessive alcohol consumption, on the other. Each of these behaviors have immediate or long-term effects upon the individual's health and are to varying extents within the individual's control. Epidemiological studies reveal great variability in who performs these behaviors. The approaches taken to understanding such individual differences have been equally varied. One can classify these approaches into those which examine factors intrinsic to the individual (e.g., sociodemographic factors, personality, social support, cognitions) and those which examine factors extrinsic to the individual. This second group of approaches can be further divided into those based on incentive structures (e.g., taxing tobacco and alcohol, subsidizing sports facilities) and those based on legal restrictions (e.g., banning dangerous substances, financial penalties for not wearing seat-belts). The first approach (factors intrinsic to the individual) has received most attention from psychologists, with a particular focus on cognitive factors as the most important proximal determinants of behavior. A variety of models of how such cognitive factors produce various "social" behaviors have been developed and are commonly referred to as social cognition models (SCMs). SCMs are recognized to have made a valuable contribution to the understanding of both who performs health behaviors (Conner & Norman, 1996b; Marteau, 1989) and how extrinsic factors produce behavior change (e.g., Rutter & Quine, 1996).

This chapter examines the key health behaviors and ways in which their adoption might be encouraged. The chapter then considers the contribution psychology has made to understanding and changing health behaviors through the development of SCMs. The most widely applied SCMs are described and reviewed along with recent developments and future prospects for this field of research.

8.01.2 KEY BEHAVIORS INFLUENCING HEALTH, MORBIDITY, AND MORTALITY

8.01.2.1 Introduction

We might define health behavior as any activity taken for the purpose of preventing or detecting disease or for improving general well-being (Conner & Norman, 1996b). The behaviors within this definition include medical service usage (e.g., physician visits, vaccination, screening), compliance with medical regimens (e.g., dietary, diabetic, antihypertensive regimens), and self-directed health behaviors (e.g., diet, exercise, smoking, alcohol consumption).

Numerous studies have examined the relationship between health behaviors and health outcomes (e.g., Black Report, 1988; Blane, Smith, & Bartley, 1990; Blaxter, 1990; Cox, Huppert, & Whichelow, 1993; Doll, Peto, Wheatley, Gray, & Sutherland, 1994; Gottlieb & Green, 1984). Such studies demonstrate the role of a variety of behaviors for both morbidity and mortality. One of the first such studies in Alameda County identified seven features of lifestyle: not smoking, moderate alcohol intake, sleeping 7–8 hours per night, exercising regularly, maintaining a desirable body weight, avoiding snacks, and eating breakfast regularly which together were associated with lower morbidity and higher subsequent long-term survival (Belloc, 1973; Belloc & Breslow, 1972; Breslow & Enstrom, 1980). Such results have been replicated in a variety of different populations (e.g., Brock, Haefner, & Noble, 1988; Metzner, Carman, & House, 1983). The impact of health behaviors upon individuals' quality of life, via delaying the onset of chronic disease and extending active life span, should also be noted (Fries, Green, & Levine, 1989; Stroebe & Stroebe, 1995). Smoking, alcohol consumption, diet, gaps in primary care services and low screening uptake are all significant determinants of poor health (Amler & Dull, 1987). Such findings have led to a focus by those interested in health promotion on changing such behaviors in order to improve health. For example, in the USA, Healthy People 2000 (USDHHS, 1990) lists increased physical activity, changes in nutrition and reductions in tobacco, alcohol, and drug use as important for health promotion and disease prevention.

Below we examine several health behaviors in more detail, focusing on their prevalence and relationship to health outcomes.

8.01.2.2 Smoking

Smoking is the behavior most closely linked with long-term negative health outcomes. Both morbidity and mortality from coronary heart disease (CHD) are increased among smokers (Doll et al., 1994; Friedman, Dales, & Ury, 1979). Moreover, there is a strong positive relationship between the number of cigarettes smoked per day and the incidence of CHD (Friedman et al., 1979). In addition, smoking has been linked to a number of cancers including cancer of the lung, throat, stomach, and bowel as well as a number of more immediate negative health effects such as reduced lung capacity and bronchitis (Royal College of Physicians, 1983). Despite the array of negative health outcomes, smokers often report positive mood effects from smoking and the use of smoking as a coping strategy (Graham, 1987).

The number of people smoking in the USA and UK has shown a steady decline over the past 20 years. Data from the General Household Survey (1992) showed that 28% of people over the age of 16 smoke in the UK. Smoking is more common among men and among unskilled manual workers (General Household Survey, 1994). A similar pattern is evident in the USA, with smoking more common among less educated, lower income, and minority groups (Rigotti, 1989). Those who quit smoking reduce the risk to their health, particularly if they quit before 35 years of age (Doll et al., 1994).

8.01.2.3 Diet

The impact of various aspects of diet upon health, morbidity, and mortality are well established (USDHHS, 1988). Whilst in the Third World the problems related to diet and health are ones of undernutrition, in the First World, the problems are predominantly linked to overconsumption of food. In Western industrialized countries the major problems are linked to excessive fat consumption and insufficient fiber, fruit, and vegetable consumption. In addition, excess consumption of calories combined with insufficient exercise has made obesity a major health problem. Diet has been implicated in cardiovascular diseases (CVDs), strokes and high blood pressure, cancer, diabetes, obesity, osteoporosis, and dental disease.

It is generally agreed that elevated blood cholesterol level is a major risk factor for the development of CVD (Consensus Development Conference on Lowering Blood Cholesterol to Prevent Heart Disease, 1985). Nutbeam and Catford (1990) estimate that 26% of men and 25% of women in the UK have cholesterol levels greater than 6.5 mmol l^{-1} (a level considered to be excessive). While in the USA, it is estimated that 50% of the adult population is at risk of CHD by virtue of elevated blood cholesterol levels (Sampos, Fulwood, Haines et al., 1989). International studies have clearly demonstrated an association between saturated fat consumption (one source of cholesterol) and blood cholesterol levels. For example, Keys (1970) reported a correlation of 0.89 across the seven countries studied. The reduction of blood cholesterol via dietary change is now widely accepted as an important way of tackling CHD (Expert Panel, 1993). Drug treatment to reduce blood cholesterol levels is generally seen as only advisable if dietary change is ineffective (Wardle, 1995). Dietary recommendations include reducing fat in the diet and increasing soluble fiber intake (Committee on Medical Aspects of Food Policy, 1991; Expert Panel, 1993). However, their impact upon cholesterol levels may be limited.

8.01.2.4 Exercise

Engaging in regular exercise is seen to be another key component of a healthy lifestyle. The potential health benefits of engaging in regular exercise are many and include reduced cardiovascular morbidity and mortality (Oberman, 1985), lowered blood pressure (Blair, Goodyear, Gibbons, & Cooper, 1984) and the increased metabolism of carbohydrates (Lennon et al., 1983) and fats (Rosenthal, Haskell, Solomon, Widstrom, & Reavan, 1983), as well as a range of psychological benefits such as improved self-esteem (Sachs, 1984), positive mood states (Folkins & Sime, 1981), reduced life stress (Brown, 1991), and reduced levels of anxiety (Singer, 1992).

However, despite the various health benefits of exercise, a significant proportion of the population lead a sedentary lifestyle. For example, the General Household Survey (1989) indicated that only one in three men and one in five women in the UK participate in any sport or recreational physical activity. Moreover, the Allied Dunbar Fitness Survey (1992) of 6000 English adults reported that one in six adults had done no exercise (i.e., for 20 minutes or more at a moderate or vigorous level) in the previous four weeks. Participation in regular exercise is strongly related to a number of socio-demographic variables. In particular, young people and males are more likely to engage in regular exercise. For example, the 1988 Welsh Heart Health Survey (Health Promotion Authority for Wales, 1990) reported that among 18–34 year olds, 61% of men engaged in moderately vigorous exercise at least two times a week compared with only 35% of women. For 35–64 year olds, the percentages drop to 37% for men and 17% for women. Overall, the typical exerciser is likely to be young, well-educated, affluent, and male (King et al., 1992).

8.01.2.5 Other Behaviors

A number of other behaviors show clear links to health. Below we briefly consider recreational drug use, safe sex, alcohol use, and health screening as behaviors with important health consequences.

The use of recreational drugs has long been recognized as a potential health problem which needs to be tackled (Aguirre-Molina & Gorman, 1996). The most commonly used drugs are alcohol and tobacco, however, here we consider what are usually referred to as psychoactive drugs (i.e., a drug that alters mood or behavior). There are a large number of such drugs including hypnotic drugs such as barbiturates which reduce anxiety and produce sedation; stimulants such as amphetamines which elevate mood, increase wakefulness, and give an enhanced sense of mental and physical energy; opiates such as opium and heroin which produce pleasant mood states; antipsychotic agents such as chlorpromazine which diminish the symptoms of psychoses; and psychedelics/hallucinogens such as LSD, cannabis, and MDMA (3,4-methylenedioxymethamphetamine) which cause visual and auditory hallucinations. Most of these drugs have medical uses as well as being used recreationally.

Data from various drug use surveys in the UK (e.g., Leitner, Shapland, & Wiles, 1993) suggest that opiate use has remained stable (at around 1%), but the use of cannabis and other nonopiates has been on the increase over the last 25 years. The 1968 OPCS survey reported that 2% of the 16 years and over age group had used cannabis at some stage, while the Leitner et al. (1993) study reported that 10% of the same age group had used it. In general, drug use in the UK does not differ substantially from the rest of the Western world. Reported lifetime usage in the USA is slightly higher than in the UK, although estimates for injecting use (1–2% of the general population), alcohol use (around 85%), and lifetime tobacco use (around 75%) are roughly similar.

Sexual behaviors have also long been considered health behaviors because of their impact upon the spread of sexually transmitted diseases (STDs) such as gonorrhoea and syphilis. More recently, the role of sexual behaviors in the spread of the human immunodeficiency virus (HIV) has been a focus of attention (O'Leary & Raffaelli, 1996). Whilst early health education campaigns emphasized the need to reduce the number of sexual partners or avoid particular sexual practices (e.g., anal sex, penetrative sex), more recently the focus has been upon the use of condoms during penetrative sex to reduce the risk of HIV transmission (Reiss & Leik, 1989). Condom use is particularly recommended for those with multiple partners or those who do not know their partners' sexual history. For these reasons, much of the health advice concerning condom use has been focused on young people.

There seems to be considerable variation in the use of condoms in response to the threat of HIV/AIDS. For example, among heterosexuals, Richard and van der Pligt (1991) reported that 50% of their sample of Dutch teenagers with multiple partners consistently used condoms. While other studies in the UK and USA report rates of between 24% and 58% (Fife-Schaw & Breakwell, 1992; Gerrard, Gibbons, & Bushman, 1996). Among homosexuals, Weatherburn, Hunt, Davies, Coxon, and McManus (1991) reported that 39% of their sample always used a condom during anal sex. Whilst among bisexuals, Boulton, Schram Evans, Fitzpatrick, and Hart (1991) report that 25% of their male sample used condoms with their current male partner and only 12% with their current female partner. The General Household Survey (1993) in the UK reported changes by age group in the use of condoms for the period 1983–1991. Among 16–24-year-olds, condom use increase from around 6% to around 12% during this period, whilst among 40–49-year-olds it dropped from around 18% to around 12% over the same period. Thus, health messages aimed at increasing condom use may be having some impact among younger people, although the overall rates of use are still worrying low.

High alcohol consumption has been linked to a range of negative health outcomes including high blood pressure (Shaper et al. 1981), heart disease (Sherlock, 1982), and cirrhosis of the liver (Colliver & Malin, 1986), although there is some evidence to suggest that low levels of alcohol consumption may have slightly beneficial effects on health (Hennekens, 1983). High levels of alcohol consumption have also been associated with accidents, injuries, suicides, crime, domestic violence, rape, murder, and unsafe sex (*British Medical Journal*, 1982). While many of the adverse effects of high alcohol consumption are due to continued heavy drinking (e.g., cirrhosis of the liver, heart disease), others are more specifically related to excessive alcohol consumption in a single drinking session (e.g., accidents, violence) (Honkanen et al., 1983).

The General Household Survey (1992) reported that the average weekly consumption of alcohol in the UK was 15.9 units (approximately 8 pints of beer) for men and 5.4 (approximately 2.5 pints of beer) for women. Of more interest was the finding that about 27% of men and 11% of women were drinking more than the recommended weekly sensible limits (21 units for men, 14 units for women). Heavy drinking is also more likely among younger age groups. In a survey of 12 000 Welsh adults, Moore, Smith, and Catford (1994) reported that 31.1% of drinkers aged 18–24 engaged in binge drinking (i.e., drinking half the recommended weekly consumption of alcohol in a single session) at least once a week.

Finally, individuals may seek to protect their health by participating in various screening programs which attempt to detect disease at an early, or asymptomatic, stage. In the UK, screening programs have been set up for various diseases including anemia (Ashworth, 1963), diabetes (Redhead, 1960), bronchitis (Gregg, 1966), cervical cancer (Freeling, 1965), and breast cancer (Forrest, 1986). Considering breast cancer, it has been estimated that breast screening programs which include mammograms can reduce breast cancer mortality by up to 40% among women aged 50 and over (Strax, 1984). However, participation rates in breast screening programs show great variability across different countries, ranging from 25% to 89% (Vernon, Laville, & Jackson, 1990). Participation tends to be negatively related to age and positively related to education level and socioeconomic status (Vernon et al., 1990).

8.01.3 UNDERSTANDING THE BASIS OF HEALTH BEHAVIOR

8.01.3.1 Introduction

A clearer understanding of why individuals perform health behaviors might assist in the development of interventions to help individuals gain the benefits of improved health and well-being. A variety of factors have been found to account for individual differences in the performance of various health behaviors, including demographic factors, social factors, emotional factors, perceived symptoms, factors relating to access to medical care, personality factors, and cognitive factors (Adler & Matthews, 1994; Rosenstock, 1974; Taylor, 1991).

Demographic variables show reliable associations with the performance of health behaviors. For example, there is a curvilinear relationship between many health behaviors and age, with high incidences of many health-risking behaviors such as smoking in young adults and much lower incidences in children and older adults (Blaxter, 1990). Such behaviors also vary by gender, with females being generally less likely to smoke, consume large amounts of alcohol, engage in regular exercise but more likely to monitor their diet, take vitamins, and engage in in dental care (Waldron, 1988). Differences by socioeconomic status and ethnic group are also apparent for behaviors such as diet, exercise, alcohol consumption, and smoking (e.g., Blaxter, 1990). Generally speaking, younger, wealthier, better educated individuals, under low levels of stress, with high levels of social support, are more likely to practice health enhancing behaviors. Higher levels of stress and/or fewer resources are associated with health-compromising behaviors such as smoking and alcohol abuse (Adler & Matthews, 1994).

Social factors seem to be important in instilling health behaviors in childhood. Parent, sibling, and peer influences are important, for example, in the initiation of smoking (e.g., McNeil et al., 1988). Cultural values also have a major impact, for instance in determining the number of women exercising in a particular culture (e.g., Steptoe & Wardle, 1996). For example, Steptoe and Wardle (1992) report that between 34% and 95% of women in their European student sample had exercised in the past 14 days. Perceived symptoms control health habits when, for example, smokers regulate their smoking on the basis of sensations in the throat. Access to medical care has been found to influence the use of such health services (e.g., Black Report, 1988). Personality factors have also been associated with health behaviors (Adler & Matthews, 1994; Steptoe et al., 1994).

Cognitive factors also determine whether or not an individual practices health behaviors. Knowledge about behavior–health links is an important factor in an informed choice concerning a healthy lifestyle. Various other cognitive variables have been studied including perceptions of health risk, efficacy of behaviors in influencing this risk, social pressures to perform the behavior, and control over performance of the behavior. The relative importance of various cognitive factors in determining who performs various health behaviors constitutes the basis of different models. Such models have been labeled SCMs because of their focus on cognitive variables as the primary determinant of individual social behaviors.

Two types of SCMs have been applied in health psychology, predominantly to explain health-related behaviors and response to treatment (Conner, 1993). The first type focus on individuals' understanding of the causes of health-related events and are best typified by attribution models (e.g., King, 1982). The second type are more diverse in nature and attempt to predict future health-related behaviors and outcomes. These include the health belief model (HBM; e.g., Becker, 1974; Janz & Becker, 1984; Sheeran & Abraham, 1996), health locus of control (HLOC; Norman & Bennett, 1996; Seeman & Seeman, 1983; Wallston, Wallston, & De Vellis, 1978), protection motivation theory (PMT; e.g., Boer & Seydel, 1996; Rogers, 1983; van der Velde & van der Pligt, 1991), theory of reasoned action/theory of planned behavior (TRA/TPB; e.g., Ajzen, 1988; 1991; Ajzen & Fishbein, 1980; Conner & Sparks, 1996), and self-efficacy (SE; e.g., Bandura, 1982, 1991; Schwarzer, 1992; Schwarzer & Fuchs, 1996). Other models include self-regulation theory (Leventhal, Nerenz, & Steele, 1984), the transtheoretical model of change (Prochaska & DiClemente, 1984), the precaution-adoption process (Weinstein, 1988), and the model of goal achievement (Bagozzi, 1992). However, none of these latter models have been widely applied to the prediction of health behaviors at present.

These social cognition models provide a basis for understanding the determinants of behavior and behavior change. Each of these models emphasize the rationality of human behavior, although they do not assume that all behavior is based upon careful thought (Ajzen, 1996). Most assume that behavior and decisions are based upon elaborate, but subjective, cost/benefit analysis of the likely outcomes of differing courses of action. As such they have roots going back to expectancy-value theory (Peak, 1955) and subjective expected utility theory (SEU; Edwards, 1954). It is assumed that individuals generally aim to maximize utility and so prefer behaviors which are associated with the highest expected utility (Van der Pligt & de Vries, 1998). Whilst such considerations may well provide good predictions of which behaviors are selected, it has been noted by several authors that they do not necessarily provide an adequate description of the way in which individuals make decisions (e.g., Edwards, 1992; Feather, 1982; Frisch & Clemen, 1994; Jonas, 1993).

In the section which follows, the most widely used of these models (HBM, TPB, HLOC, PMT, SE) are outlined, the research using them described, and their use reviewed.

8.01.3.2 Health Belief Model

8.01.3.2.1 Model description

The HBM is probably the most widely used social cognition model in health psychology (Becker, 1974; Rosenstock, 1966; Sheeran & Abraham, 1996). It was originally developed by US public health researchers attempting to develop models upon which to base health education programs (Hochbaum, 1958; Rosenstock, 1966). The model attempts to conceptualize the health beliefs which make a behavior more or less attractive. In particular, the key health beliefs were seen to be the likelihood of experiencing a health problem, the severity of the consequences of the health problem, and the perceived costs and benefits of the health behavior. Thus, the HBM employs two aspects of individuals' representations of health behavior in response to threat of illness: perceptions of the threat of illness and evaluation of the effectiveness of behaviors to counteract this threat (see Figure 1). Threat perceptions depend upon two beliefs: the perceived susceptibility to the illness and the perceived severity of the consequences of the illness. Together these two variables determine the likelihood of the individual following a health-related action, although their effect is modified by individual differences in demographic variables, social pressure, and personality. The particular action taken is determined by evaluation of the possible alternatives. This behavioral evaluation depends upon beliefs concerning the benefits or efficacy of the health behavior and the perceived costs or barriers to performing the behavior. Hence, individuals are likely to follow a particular health action if they believe themselves to be susceptible to a particular condition or illness which they consider to be serious, and believe the benefits of the action taken to counteract the condition or illness outweigh the costs. Cues to action and health motivation are two other variables commonly included in the model. Cues to action include a diverse range of triggers to the individual taking action and are commonly divided into factors which are internal (e.g., physical symptom) or external (e.g., mass media campaign, advice from others such as physicians) to the individual (Janz & Becker, 1984).

Becker (1974) has argued that the HBM should also contain a measure of health motivation (readiness to be concerned about health matters) because certain individuals may be predisposed to respond to cues to action because of the value they place on their health. Other influences upon the performance of health behaviors, such as demographic factors or psychological characteristics (e.g., personality, peer pressure, perceived control over behavior), are assumed to exert their effect via changes in the six components of the HBM. This is a potentially important issue if the HBM is to claim to be a complete model of health behavior. However, this has not been widely addressed in empirical studies and where it has the evidence has been equivocal. Orbell, Crombie, and Johnson (1995), for example, reported that HBM components did mediate the effects of social class upon uptake of cervical screening, but did not mediate the effects of marital status or sexual experience.

8.01.3.2.2 Review of research

The HBM has been applied to a very broad range of health behaviors and populations. Sheeran and Abraham (1996) distinguish three broad areas of research. First, the HBM has been applied to various preventive health behaviors. These include health-risk behaviors such as smoking (Gianetti, Reynolds, & Rihen, 1985; Stacey & Lloyd, 1990) and alcohol use (K. H. Beck, 1981; Gottlieb & Baker, 1986), as well as health-promoting behaviors such as diet (Aho, 1979), exercise (Langlie, 1977), genetic (Becker, Kaback, Rosenstock, & Ruth, 1975) and health screening (Conner & Norman, 1994; King, 1982), vaccination (Oliver & Berger, 1979), breast self-examination (Champion, 1984; Ronis & Harel, 1989), contraceptive use (Hester & Macrina, 1985), and dental behaviors (Chen & Land, 1986). A second area the HBM has been applied to is various sick role behaviors which refer to compliance with professionally recommended medical regimens in response to illness. These include compliance with antihypertensive regimens (Taylor, 1979), diabetic regimens (Harris & Lynn, 1985), and renal disease regimens (Hartman & Becker, 1978), and regimens adhered to by parents for a child's condition (Becker, Radius, & Eveland, 1978). Third, the HBM has been applied to clinic use, which includes physician visits for a variety of reasons including preventative (Aiken, West, Woodward, Reno, & Reynolds, 1994), psychiatric (Connelly, 1984), and parent and child conditions (Kirscht, Becker, & Eveland, 1976). There is no strong evidence that the HBM has been more predictive of behavior in any one of these behaviors compared with any other (Sheeran & Abraham, 1996).

There have been two quantitative reviews of research with the HBM (Harrison, Mullen, & Green, 1992; Janz & Becker, 1984). The first, conducted by Janz and Becker (1984), examined the proportion of times each of the HBM's components showed a significant relationship with health behavior through the use of a "significance ratio." Across the 46 studies reviewed, the barriers component was found to have the most consistent relationship with health behavior (89%), followed by the susceptibility (81%), benefits (78%), and severity (65%) components. However, while Janz and Becker (1984) suggest that the HBM components are consistent predictors of health behavior, they fail to estimate the strength of the relationships. This question was addressed in the second quantitative review, conducted by Harrison et al. (1992). Over 200 published studies on the HBM were identified although only 16 of these were found to measure each of the components adequately. Harrison et al's (1992) meta-analysis on these 16 studies produced a similar pattern of results to Janz and Becker's (1984) earlier review with the barriers components having the highest average correlation with health behavior ($r = -0.21$), followed by the susceptibility ($r = 0.15$), benefits ($r = 0.13$), and severity ($r = 0.08$) components. The predictive power of individual components is therefore relatively modest, accounting for only 0.5–4% of variance in behavior. However, it should be noted that it is the combined effects of the six health beliefs which is generally of interest and this is commonly in excess of the sum of the effects of the individual components.

8.01.3.2.3 Commentary

The HBM has provided a useful framework for investigating health behaviors and identifying key health beliefs, has been widely used, and has met with moderate success in predicting a range of health behaviors (for reviews see Harrison et al., 1992; Janz & Becker, 1984; Sheeran & Abraham, 1996). The strength of the HBM lies in the fact that it was developed by researchers working directly with health behaviors and so many of the concepts possess face-validity to those working in this area. This commonsense operationalization of a number of cognitive variables relevant to the performance of health behavior partly account for the model's popularity.

However, compared to other similar social cognitive models of health behaviors, the HBM suffers from a number of weaknesses. The way in which the variables in the HBM combine to produce behavior has not been precisely specified (but see Becker & Rosenstock, 1987) and so the HBM is thus frequently tested as six independent predictors of behavior. In addition, various researchers have used somewhat different operationalizations of the six constructs (see Becker & Maiman, 1983; Rosenstock, 1974). Together these factors have weakened the status of the HBM as a coherent SCM of health behavior (Conner, 1993; Sheeran & Abraham, 1996). Moreover, key social cognitive variables, found to be highly predictive of behavior in other models, are not incorporated in the HBM. For example, intentions to perform a behavior and social pressure are key components of the TRA/TPB which do not appear in the HBM. Also, perceptions of personal control over the performance of the behavior (self-efficacy beliefs) which have been found to be such powerful predictors of behavior in models based upon social cognitive theory (Bandura, 1982; Schwarzer & Fuchs, 1996) are not explicitly included in the HBM. In addition, in not specifying a causal ordering among the variables, as is done in other models, more powerful analysis of data and clearer indications of how interventions may have their effects are precluded in the HBM. Several authors have noted, for example, that threat is perhaps best seen as a more distal predictor of behavior acting via influences upon outcome expectancies. Finally, the model is static; there is no distinction between a motivational stage dominated by cognitive variables and a volitional phase where action is planned, performed, and maintained (Schwarzer, 1992). Such distinctions are thought to be important in understanding various health behaviors. Hence, while an extremely popular SCM for use in understanding health behavior, it is also in a number of ways limited and may receive relatively less attention in the future.

8.01.3.3 Theory of Planned Behavior

8.01.3.3.1 Model description

The TPB was developed by social psychologists and has been widely applied to the understanding of a variety of behaviors including health behaviors (Ajzen, 1988, 1991; Conner & Sparks, 1996) (see Figure 2). The TPB details how the influences upon an individual determine that individual's decision to follow a particular behavior. This theory is an extension of the widely applied TRA (Ajzen & Fishbein, 1980; Fishbein & Ajzen, 1975). The TPB suggests that the proximal determinants of behavior are intentions to engage in that behavior and perceived behavioral control over that behavior. Intentions represent a person's motivation in the sense of his or her conscious plan or decision to exert effort to perform the behavior. Perceived behavioral control is a person's expectancy that performance of the behavior is within his/her control. The concept is similar to Bandura's (1982) concept of self-efficacy (see Schwarzer & Fuchs, 1996). Control is seen as a continuum with easily-executed behaviors at one end and behavioral goals demanding resources, opportunities, and specialized skills at the other.

Intentions are determined by three variables. The first is attitudes, which are the overall evaluations of the behavior by the individual. The second is subjective norms, which consist of a person's beliefs about whether significant others think he/she should engage in the behavior. The third is perceived behavioral control (PBC), which is the individual's perception of the extent to which performance of the behavior is within his/her control. In addition, to the extent that PBC reflects actual control, it is predicted to directly influence behavior.

Just as intentions are held to have determinants, so the attitude, subjective norm, and perceived behavioral control components are also held to have determinants. The attitude component is a function of a person's salient behavioral beliefs, which represent perceived likely consequences of the behavior. Following expectancy-value conceptualizations (Peak, 1955), the model quantifies consequences as being composed of the multiplicative combination of the judged likelihood that performance of the behavior will lead to a particular outcome and the evaluation of that outcome. These expectancy-value products are then summed over the salient consequences. It is not claimed that individuals perform such calculations each time they are faced with a decision about whether to perform a behavior or not, but rather the results of such considerations are maintained in memory and retrieved and used when necessary (Eagly & Chaiken, 1993). However, it is also possible for the individual to retrieve the relevant beliefs and evaluations when necessary.

Subjective norm is a function of normative beliefs, which represent perceptions of specific salient others' preferences about whether one should or should not engage in a behavior. In the model, this is quantified as the subjective likelihood that specific salient groups or individuals (referents) think the person should or should not perform the behavior, multiplied by the person's motivation to comply with that referent's expectation. Motivation to comply is the extent to which the person wishes to comply

with the specific wishes of the referent on this issue. These products are then summed across salient referents. Judgments of perceived behavioral control are influenced by beliefs concerning access to the necessary resources and opportunities to perform the behavior successfully, weighted by the perceived power of each factor (Ajzen, 1988, 1991). The perception of factors likely to facilitate or inhibit the performance of the behavior are referred to as control beliefs. These factors include both internal control factors (information, personal deficiencies, skills, abilities, emotions) and external control factors (opportunities, dependence on others, barriers). People who perceive they have access to the necessary resources and perceive that there are the opportunities (or lack of obstacles) to perform the behavior are likely to perceive a high degree of behavioral control (Ajzen, 1991). Ajzen (1991) has suggested that each control factor is weighted by its perceived power to facilitate or inhibit performance of the behavior. The model quantifies these beliefs by multiplying the frequency or likelihood of occurrence of the factor by the subjective perception of the power of the factor to facilitate or inhibit the performance of the behavior.

So, according to the TPB, individuals are likely to follow a particular health action if they believe that the behavior will lead to particular outcomes which they value, if they believe that people whose views they value think they should carry out the behavior, and if they feel that they have the necessary resources and opportunities to perform the behavior.

8.01.3.3.2 Review of research

The TPB has been applied to the prediction of a number of different behaviors including health-relevant behaviors with varying degrees of success (Ajzen, 1991; see Conner & Sparks, 1996 for a review of the application of the TPB to health behaviors). For example, smoking has been a focus of several studies (Babrow, Black, & Tiffany, 1990; Godin, Valois, Lepage, & Desharnais, 1992). Godin et al. (1992) looked at the prediction of the frequency of smoking in the general public over a six-month period. The prediction of intentions was significantly improved by the addition of the PBC component, and actual smoking behavior appeared to be primarily related to PBC. One study has examined drinking alcohol (Schlegel, D'Avernas, Zanna, & DeCourville, 1992) and found that PBC contributed to the predictions of intentions but not the frequency of getting drunk in nonproblem drinkers, while in problem drinkers, the PBC also contributed to predictions of frequency of getting drunk.

Several studies examined condom use (Boldero, Moore, & Rosenthal, 1992; Wilson, Zenda, McMaster, & Lavelle, 1992). Nucifora, Gallois, and Kashima (1993), for example, examined undergraduates' use of condoms using the TPB. PBC was found to make a small but significant contribution to the predictions of intentions to use condoms and actual condom use. However, intentions appeared to be principally determined by attitudes and subjective norms, while behavior was mainly influenced by intentions. Exercise has also been examined in several studies (Dzewaltowski, Noble, & Shaw, 1990; Godin & Shepherd, 1987; Norman & Smith, 1995). Dzewaltowski et al. (1990) reported the application of the TPB to exercise participation. Intentions were based both upon attitudes and PBC, but not subjective norms, whilst actual behavior seemed to be principally determined by intentions. Breast or testicle self-examination has been the focus of a couple of studies (McCaul, Sandgren, O'Neill, & Hinsz, 1993; Young, Lierman, Powell-Cope, & Kasprzyk, 1991). McCaul et al. (1993) showed the TRA components to predict breast/testicle self-examination intentions and behaviors, with PBC adding significantly to predictions of intentions but not behavior.

A range of other behaviors have been examined using the TPB, including health screening attendance (DeVellis, Blalock, & Sandler, 1990; Norman & Conner, 1993), food choices (Beale & Manstead, 1991; Sparks & Shepherd, 1992), kidney donation (Borgida, Conner, & Manteufel, 1992), drug compliance (Hounsa, Godin, Alihonou, & Valois, 1993), patient education (Kinket, Paans, & Verplanken, 1992), and weight control (Netemeyer, Burton, & Johnston, 1991; Schifter & Ajzen, 1985).

The published studies applying the TRA have been reviewed by Sheppard, Hartwick, and Warshaw (1988) and van den Putte (1993), with Ajzen (1991) reviewing 16 studies using the TPB. The findings are generally supportive of the TRA/TPB. Ajzen (1991) reports the multiple correlation between intentions and attitude, subjective norm and PBC to be 0.71 across the 16 studies he reviewed. Van den Putte (1993) computes a value of $r = 0.64$, but notes the large variation in results between behaviors. Ajzen reports the mean correlation between intentions, PBC and behavior to be 0.51, while van den Putte computes a value of 0.46. Ajzen (1991) and Madden, Ellen, and Ajzen (1992) report empirical evidence that PBC significantly improves predictions of both intentions and behavior. Hence, in summary, the evidence is broadly supportive of the TPB in helping to understand and predict health behaviors. The relative importance of the different predictors is largely an empirical matter. However, in terms of predictors of intentions, it has been argued that attitude may be more important than subjective norms for health behaviors performed in private (e.g., breast self-examination), while subjective norm may be more important than attitudes where the behavior is performed in public (e.g., safety helmet use) (Quine, Rutter, & Arnold, 1998).

8.01.3.3.3 Commentary

The TPB has been widely tested and successfully applied to the understanding of a variety of behaviors (for reviews see Ajzen, 1991; Conner & Sparks, 1996; Sheppard et al., 1988). The theory incorporates a number of important cognitive variables which appear to determine health behaviors (intentions, expectancy values, perceived behavioral control). Also the role of social pressure from others is incorporated in the model in the form of subjective norms. However, perhaps because the model was developed outside the health arena, the model does not make an assessment of health threat as is included in models such as the HBM. Finally, the theory states a clear causal ordering among variables in how they relate to behavior, allowing sophisticated analysis techniques to be applied to assessing the model.

Sheppard et al. (1988), in a review of the TRA, have argued for the need to consider both behavioral intentions and self-predictions when predicting behavior. Warshaw and Davis (1985) noted a number of different ways in which intentions had been measured, and distinguished measures of behavioral intentions (e.g., "I intend to perform behavior x") and from measures of self-predictions (e.g., "How likely is it that you will perform behavior x?"). This distinction is important when considering the prediction of health behavior because while, for example, David might intend to quit smoking, he might also think that it is unlikely that he will do so. Sheppard et al. went on to argue that self-predictions should provide better predictions of behavior as they are likely to include a consideration of those factors which may facilitate or inhibit performance of a behavior as well as a consideration of the likely choice of other competing behaviors. Sheppard et al.'s meta-analysis supports this view; measures of self-predictions were found to have stronger relationships with behavior than behavioral intentions. However, Norman and Smith (1995) found no difference in the extent to which the two measures correlated with exercise behavior. Furthermore, the measures of behavioral intentions and self-predictions are strongly correlated, suggesting that the discriminant validity for the two concepts may be weak. Bagozzi (1992) notes that the causal path may begin with the formation of desires which then develop into intentions, which in turn inform self-predictions. However, Conner and Sparks (1996) note that while theoretically these concepts may be distinguishable, empirically there is little to distinguish the three concepts. Clearly, more work is needed to further disentangle these and other related constructs that have appeared in the literature such as planning and commitment (Bagozzi, 1992, 1993), need to change (Paisley & Sparks, 1998), and behavioral willingness (Gibbons, Gerrard, Ouelette, & Burzette, 1998).

Self-efficacy is a powerful predictor of the performance of a range of health behaviors (Schwarzer & Fuchs, 1996). Ajzen (1991) argues that the PBC and self-efficacy constructs are interchangeable. However, several authors (e.g., Terry & O'Leary, 1995) have suggested that self-efficacy and PBC are not entirely synonymous. Bandura (1986), for example, argues that control and self-efficacy are quite different concepts. Although Bandura (1986) accepts that some external factors (e.g., task difficulty) will have an influence on self-efficacy, it may still be argued that self-efficacy is more concerned with perceptions of control based on internal control factors. In contrast, PBC is likely to reflect more external factors, and may be more usefully described as "perceptions of control over the behavior" (Armitage & Conner, in press). For example, Terry and O'Leary (1995) measure self-efficacy over exercising by items such as "For me to exercise would be ... easy–difficult" and perceived control over the behavior by "How much control do you have over exercising? no control–complete control."

De Vries, Dijkstra, and Kuhlman (1988) have advocated the use of measures of self-efficacy as opposed to PBC in the prediction of intentions and behavior. Further, Dzewaltowski et al. (1990), in a comparison of the TRA, TPB, and Bandura's (1986) Social Cognitive Theory, found that self-efficacy rather than PBC had a direct impact on behavior. Terry and O'Leary (1995) examined exercise behavior and found that self-efficacy only predicted intentions, while PBC had main and interactive effects on exercise behavior. Crucially, a combined measure of PBC and self-efficacy failed to moderate the effect of intention on behavior, suggesting that the two constructs are not synonymous. This issue warrants further empirical study. It seems plausible, however, that perceptions of control and self-efficacy are two separable constructs which not only have differential effects on intentions and behavior but may act differently for different behaviors.

The TPB is correctly regarded as a theory of the proximal determinants of behavior. Indeed, Ajzen (1991) describes the model as open to further elaboration if further important proximal determinants are identified. A number of potential candidate variables for addition to the TRA/TPB have been suggested. In each case both theoretical and empirical justifications are necessary (Fishbein, 1993). Some of the most promising of these "additional variables" are considered in Section 8.01.5.2.

8.01.3.4 Health Locus of Control

8.01.3.4.1 Model description

The HLOC construct is one of the most widely researched constructs in relation to the prediction of health behavior (K. A. Wallston, 1992). Its origins can be traced back to Rotter's (1954) social learning theory which states that the likelihood of a behavior occurring in a given situation is a function of the individual's expectancy that the behavior will lead to a particular reinforcement and the extent to which the reinforcement is valued. As well as being applied on a specific level, Rotter argued that social learning theory could be applied on a general level such that individuals may have generalized expectancy beliefs which cut across situations. It was at this generalized level that Rotter introduced the distinction between internal and external locus of control orientations, with "internals" believing that events are a consequence of their own actions and thereby under personal control and "externals" believing that events are unrelated to their actions and thereby beyond their personal control.

Early work examining the relationship between locus of control and health behavior with Rotter's (1966) Internal–External (I–E) scale produced mixed results. However, the I–E scale was criticized for being too generalized to predict health behavior and for conceptualizing locus of control as a unidimensional construct. In particular, Levenson (1974) argued that internal locus of control beliefs are orthogonal to external locus of control beliefs, and that within external locus of control a distinction can be made between external control exerted by powerful others and the influence of chance or fate. The development of the multidimensional health locus of control (MHLC) Scale (K. A. Wallston et al., 1978) addressed both these criticisms, and has since become the most popular locus of control measure in research on health behavior (Wallston & Wallston, 1981, 1982).

The MHLC scale measures generalized expectancy beliefs with respect to health along three dimensions. These measure the extent to which individuals believe their health is a function of their own actions (i.e., internal HLOC), the actions of powerful others such as health professionals (i.e., powerful others HLOC), and the influence of chance or fate (i.e., chance HLOC). According to HLOC theory, individuals who have strong internal HLOC beliefs should be more likely to engage in health-promoting behaviors. Conversely, those who believe that their health is due to chance or fate should be less likely to engage in health-promoting behaviors. The prediction for powerful others HLOC is less clear cut. Strong powerful others HLOC beliefs may reflect a receptivity to health messages endorsed by health professionals. Alternatively, strong powerful others HLOC beliefs may indicate a strong belief in the ability of health professionals to cure subsequent illnesses and may be unrelated or negatively related to the performance of health-promoting behaviors.

According to social learning theory, the above relationships should only hold for individuals who place a high value on their health as behavior is a function of both expectancy beliefs (e.g., HLOC) and the value attached to certain outcomes (e.g., health value). As K. A. Wallston (1991) argues, individuals are unlikely to engage in health-promoting behaviors if they place a low value on their health, whatever their HLOC beliefs. Thus, health value should act as a moderator of the relationship between HLOC and health behavior.

8.01.3.4.2 Review of research

The majority of the research using the HLOC construct has correlated HLOC beliefs with the performance of health behavior, without paying attention to the potential moderating role of health value. This may be due to a lack of appreciation of the complexity of social learning theory (Wallston, 1991) and/or an unchallenged assumption that all people value their health (Lau, Hartman, & Ware, 1986).

Several studies have examined the relationship between HLOC beliefs and general indices of health behavior. Most of these have reported a positive correlation between internal HLOC beliefs and the performance of health-promoting behaviours (Duffy, 1988; Mechanic & Cleary, 1980; Seeman & Seeman, 1983; Waller & Bates, 1992; Weiss & Larsen, 1990), although other studies have failed to find such a relationship (Brown, Muhlenkamp, Fox, & Osborn, 1983; Muhlenkamp, Brown, & Sands, 1985; Norman, 1995; Steptoe et al., 1994; Wurtele, Britcher, & Saslawsky, 1985). Some studies have found a negative relationship between chance HLOC beliefs and health behavior indices (Brown et al., 1983; Duffy, 1988; Muhlenkamp et al., 1985; Steptoe et al., 1994). Finally, powerful others HLOC beliefs have rarely been found to predict the performance of health-promoting behaviors (Brown et al., 1983; Duffy, 1988; Muhlenkamp et al., 1985; Steptoe et al., 1994; Waller & Bates, 1992; Weiss & Larsen, 1990). The above results are generally in line with predictions, although the relationship between HLOC and health behavior is typically a weak one.

A similar pattern of results is obtained for the relationship between HLOC beliefs and specific health behaviors. For example, studies have reported a link between internal HLOC beliefs and exercise (Carlson & Petti, 1989; O'Connell & Price, 1982; Slenker, Price, & O'Connell, 1985), while other studies have found only a weak link or no link (Burk & Kimiecik, 1994; Calnan, 1989; Liao, Hunter & Weinman, 1995; Norman, 1990, 1995; Speake, Cowart, & Stephens, 1991). In a large-scale representative sample, Calnan (1989) found significant negative correlations between the powerful others and chance HLOC dimensions and exercise.

In relation to alcohol consumption, a number of early studies used the locus of control construct to compare alcoholics with nonalcoholics producing mixed results (Butts & Chotlas, 1973; Costello & Manders, 1974). More recent work with the HLOC construct has produced similar mixed results with a number of studies finding no relationship between HLOC beliefs and drinking behavior (Dean, 1991; Liao et al., 1995; Norman, 1990, 1995) and Calnan (1989) only finding weak negative correlations between powerful others and chance HLOC beliefs and alcohol consumption.

A number of studies have applied the HLOC construct to the prediction of smoking cessation. A few of these studies have found internal HLOC beliefs to be related to smoking cessation (Horwitz, Hindi-Alexander, & Wagner, 1985; Rosen & Shipley, 1983). Other studies have failed to find a relationship between internal HLOC beliefs and smoking cessation (Kaplan & Cowles, 1978; Segall & Wynd, 1990; Wojcik, 1988). Smokers who believe that their health is under the control of powerful others might be expected to be more successful in giving up smoking after attending a formal smoking cessation program. However, a couple of studies suggest that strong powerful others HLOC beliefs are related to a greater likelihood of relapse following attendance at a smoking cessation program (Segall & Wynd, 1990; Wojcik, 1988).

Studies examining the relationship between HLOC beliefs and the performance of breast self-examination among women have found a positive relationship with internal HLOC beliefs (Redeker, 1989) and a negative relationship with powerful others HLOC beliefs (Hallal, 1982; Nemeck, 1990). The negative relationship with powerful others HLOC beliefs may reflect a belief that breast examination is the responsibility of health professionals. In support of this view, Bundek, Marks, and Richardson (1993) found a positive relationship between gynecological screening including physician breast examination and powerful others HLOC beliefs, and a positive relationship between self breast examination and internal HLOC beliefs. However, other studies have failed to find any relationship between HLOC beliefs and breast self-examination (Lau et al., 1986; Liao et al., 1995; Seeman & Seeman, 1983).

Those studies that have tested the moderating role of health value have generally produced positive results. Considering the prediction of indices of health behavior first, Weiss and Larsen (1990) found a significant correlation between internal HLOC beliefs and a health behavior index among individuals placing a high value on their health, but a nonsignificant correlation among individuals placing a low value on their health. Similar results have been reported by a number of researchers (Lau, 1982; Lau et al., 1986; Seeman & Seeman, 1983; K. A. Wallston & Wallston, 1980), although other studies have failed to find evidence for the moderating role of health value (Norman, 1995; Wurtele et al., 1985). Studies looking at the interaction between health value and the powerful others and chance dimensions have generally produced nonsignificant results (Lau et al., 1986; Wurtele et al., 1985).

A similar pattern of results emerges when the performance of specific health behaviors is considered. Evidence for an interaction between internal HLOC beliefs and health value has been found for a range of behaviors including dietary behavior (Hayes & Ross, 1987), smoking cessation (Kaplan & Cowles, 1978), breast self-examination (Lau et al., 1986), and information seeking (K. A. Wallston, Maiders, & Wallston, 1976). However, other studies have failed to find evidence for such an interaction when considering cancer-preventive behavior (McCusker & Morrow, 1979), exercise (Burk & Kimiecik, 1994), attendance at health checks (Norman, 1991), and information seeking (De Vito, Bogdanowicz, & Reznikoff, 1982).

8.01.3.4.3 Commentary

Reviews of research with the HLOC construct have concluded that HLOC is a weak predictor of health behavior, even when considered in conjunction with health value (Norman & Bennett, 1996; K. A. Wallston, 1991, 1992). There are a number of reasons for this poor performance which are outlined below.

K. A. Wallston and Wallston (1981, 1982) have argued that certain combinations of HLOC beliefs may be important in predicting health behavior. For example, when being advised to quit smoking by a health professional, it may be advantageous to have a combination of strong powerful others *and* internal HLOC beliefs. K. A. Wallston and Wallston (1981) have therefore proposed a 2 × 2 × 2 typology based on median splits on the three HLOC dimensions (see also Waller and Bates, 1992). Using this typology, "believers in control" (i.e., high internal high powerful others, low chance HLOC beliefs) have been found to show better adjustment in relation to rheumatoid arthritis (Roskam, 1986) and diabetes (Bradley, Lewis, Jennings, & Ward, 1990). To date, this approach has not been applied to the prediction of health behavior. However, despite the promise of this approach, its utility may be limited given that large sample sizes are required in order to compare all eight types. In addition, this approach may lead to results which are difficult to interpret, given the large number of comparisons.

A number of researchers have questioned the way in which health value is measured. Typically, health value has been measured as an *absolute* value using Lau et al.'s (1986) four-item scale. However, when deciding whether or not to perform a specific health behavior, individuals are often faced with more appealing alternatives. As a result, values other than health may be important in determining behavior. In such cases it may be more appropriate to use *relative* measures of health value. Kristiansen (1986) followed this approach and found that a measure of the value placed on health relative to value of an exciting life was more predictive of health behavior among young people than an absolute measure of health value. However, Wurtele et al. (1985) reported the opposite pattern of results in a sample of female undergraduates. Clearly, more work is needed comparing different approaches to the measurement of health value.

The need to consider behavior-specific control beliefs has been highlighted by a number of researchers. In particular it is possible to argue that one reason for the relatively poor performance of the HLOC construct is that it measures generalized expectancy beliefs with respect to health. In other words, while HLOC is specific to a given goal (i.e., health), it cuts across many situations (e.g., smoking, exercise, diet, etc.). As a result, the development of behavior-specific HLOC scales has been advocated. Georgiou and Bradley's (1992) smoking-specific locus of control scale is a good example of such a scale. This scale was found to have stronger correlations with smokers' behaviors and intentions than the more generalized MHLC scale. Other scales have been developed in relation to exercise (Burk & Kimiecik, 1994), AIDS risk behavior (Kelley et al., 1990), weight loss (Saltzer, 1982), alcohol use (Donovan & O'Leary, 1978) and a range of specific conditions including diabetes (Bradley et al., 1990), arthritis (Nicassio, Wallston, Callahan, Herbert, & Pincus, 1985), cancer (Prwun et al., 1988), hypertension (Stanton, 1987) and heart and lung disease (Allison, 1987). Generally, these scales have been found to be more predictive of health behavior than more generalized measures (Lefcourt, 1991).

In conclusion, the amount of variance in health behavior explained by the HLOC construct is low, even when considered in conjunction with health value (Norman & Bennett, 1996; K. A. Wallston, 1991, 1992). Nevertheless, the pattern of results obtained are generally in line with predictions suggesting that HLOC beliefs may have a distal influence on health behavior. In line with this position, K. A. Wallston (1992) has proposed a "modified social learning theory" in which health behavior is a function of HLOC beliefs, health value, and self-efficacy. Importantly, internal HLOC beliefs are seen to be a necessary, but not sufficient, condition for performing a health behavior. To date, there have been no formal tests of this modified theory, although the attempt to embed HLOC beliefs into a broader theoretical perspective is an encouraging development.

8.01.3.5 Protection Motivation Theory

8.01.3.5.1 Model description

Protection motivation theory (Rogers, 1983) was originally developed as a framework for understanding the effectiveness of health-related persuasive communications, although more recently it has also been used to predict health protective behavior. It has its origins in early work on the persuasive impact of fear appeals, which was concerned with the conditions under which fear appeals may influence attitudes and behavior. In an extension of the fear-drive model, Janis (1967) proposed that if a persuasive communication successfully arouses fear, usually through emphasizing the severity of a threat and the likelihood of its occurrence, individuals will be motivated to reduce this unpleasant emotional state. If the message also contains recommendations for action, then one way in which individuals can reduce this state of arousal is to follow the communicator's advice. If the message does not contain effective behavioral advice, then maladaptive coping reactions may follow such as denial or avoidance. Janis proposed that fear appeals may be most effective when a medium level of fear is evoked. Under such conditions the cognitive responses that promote adaptive reactions (e.g., following behavioral advice) outweigh those that promote maladaptive reactions (e.g., denial). However, later work has failed to confirm this hypothesis (Sutton, 1982).

Leventhal (1970) made a similar distinction between adaptive and maladaptive reactions in the parallel response model which differentiates between two independent control processes that are initiated by a fear appeal. The first, fear control, focuses on attempts to reduce the emotional threat (e.g., avoidance) while the second, danger control, focuses on attempts to reduce the threatened danger (e.g., following behavioral advice). The parallel response model is important in proposing that protection motivation results from danger control processes (i.e., cognitive responses) rather than from fear control processes (i.e., emotional responses).

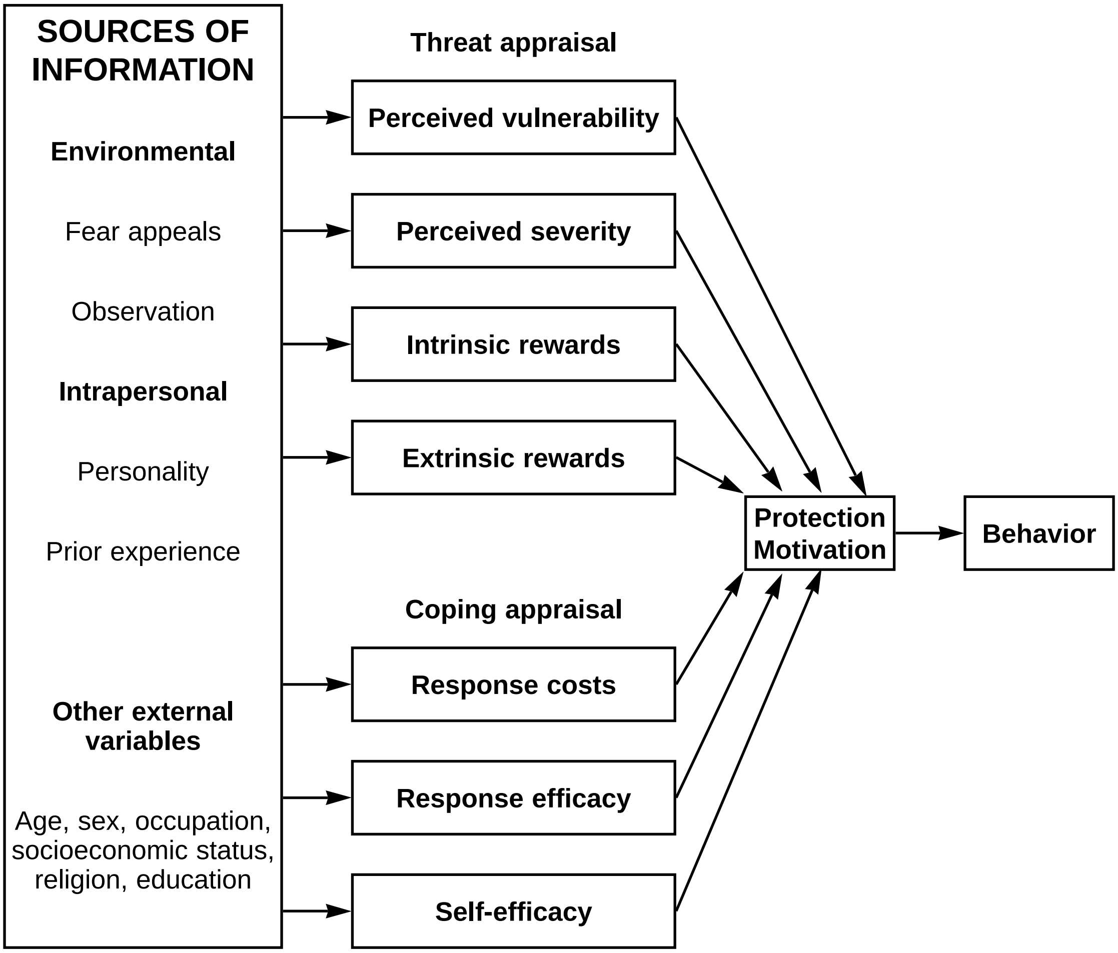
Roger's (1983) (PMT) outlines the cognitive responses resulting from fear appeals in more detail (see Figure 3). It is argued that various environmental (e.g., fear appeals) and intrapersonal (e.g., personality variables) sources of information can initiate two appraisal processes: threat appraisal and coping appraisal. Threat appraisal, which is similar to Lazarus and Launier's (1978) primary appraisal, focuses on the source of the threat and the factors that may increase or decrease the probability of the maladaptive response. Both the perceived severity of the threat and the individual's perceived vulnerability to the threat are seen to inhibit maladaptive responses. However, there may be a number of intrinsic (e.g., pleasure) and extrinsic (e.g., social approval) rewards which may serve to increase the likelihood of maladaptive responses. Coping appraisal, which is similar to Lazarus and Launier's (1978) secondary appraisal, focuses on one's ability to cope with the threat and the factors that may increase or decrease the probability of an adaptive response. Both the belief that the recommended action will be effective in reducing the danger (i.e., response efficacy) and the belief that one is capable of performing the recommended action (i.e., self-efficacy) are likely to increase the probability of an adaptive response, although various response costs (e.g., financial cost) associated with performing an adaptive response will serve to inhibit such a response.

Protection motivation results from the two appraisal processes and is a positive function of beliefs about severity, vulnerability, response efficacy, and self-efficacy, and a negative function of beliefs about the rewards associated with the maladaptive response and the response costs of the protective behavior. Moreover, for protection motivation to be elicited, it is necessary for the rewards associated with the maladaptive response to be outweighed by perceptions of severity and vulnerability, and the response costs of the protective behavior to be outweighed by perceptions of response efficacy and self-efficacy. Protection motivation, which is usually measured by behavioral intentions, is seen to arouse, direct, and sustain protective behavior.

8.01.3.5.2 Review of research

Protection motivation theory provides a framework for understanding both the effects of fear appeals and the social cognitive variables underlying health behavior. As a result, tests of PMT have taken two forms. In the first, the key components of PMT are manipulated in persuasive communications and their effects on protection motivation tested (see Section 8.01.4.1). In the second, PMT is considered as a general attitude–behavior model and its components used as predictors of health behavior. This work is reviewed below.

One area in which PMT has been used as a general attitude–behavior model is in relation to cancer-related preventive behavior. In one of the few longitudinal tests of PMT, Hodgkins and Orbell (1998) examined the social cognitive predictors of breast self-examination (BSE) in a sample of young women (17–40 year olds) over a one-month period. Each of the main components of PMT was measured (i.e., severity, vulnerability, response efficacy, self-efficacy) as well as the response costs of performing BSE (e.g., I would feel awkward examining my breasts). In a path analysis, only self-efficacy was related to intentions to perform BSE. Time one behavioral intention was in turn found to be the most important predictor of performance of BSE at one month follow-up. Similar results have been reported by Seydel, Taal, and Wiegman (1990) who found response efficacy and self-efficacy to be predictive of intentions to engage in, and concurrent performance of, a number of cancer-related preventive behaviors. Boer and Seydel (1996) also found response efficacy and self-efficacy to be predictive of intentions to participate in mammography screening.



SOURCES OF INFORMATION
Environmental
Fear appeals

Self-efficacy
Protection Motivation
Behavior

Figure 3 Protection motivation theory.

A second area of application of PMT has been in relation to AIDS risk-reducing behaviors such as condom use. Aspinwall, Kemeny, Taylor, Schneider, and Dudley (1991) examined the ability of the PMT components to predict reductions in a number of AIDS risk-reducing behaviors in a sample of gay men over a six-month period. The results showed that strong levels of self-efficacy and a high level of perceived vulnerability at time one were predictive of a reduction in the number of sexual partners over the six-month follow-up period. In addition, self-efficacy also emerged as the most important predictor of reductions in the number of anonymous sexual partners.

Van der Velde and van der Pligt (1991) used PMT as a framework for assessing the coping responses of heterosexual men and women and homosexual men with multiple partners. Considering the heterosexual sample first, it was found that vulnerability, response efficacy, and self-efficacy all had a direct positive effect on behavioral intentions to use condoms. In addition, severity had an indirect effect on behavioral intentions through a measure of fear. Similar results were found with the homosexual sample with response efficacy, self-efficacy, and severity having a positive effect on behavioral intentions to engage in safe sex. However, contrary to expectations, a negative relationship was found between vulnerability and behavioral intentions.

In a sample of male and female adolescents, Abraham, Sheeran, Abrams, and Spears (1994) found that self-efficacy had a positive influence and response costs (i.e., concern about reputation) had a negative influence on behavioral intentions to use a condom. In addition, vulnerability had a negative effect on behavioral intentions to limit the number of sexual partners. In a cross-sectional study of male and female heterosexuals, Bengel, Beltz-Merk, and Farin (1996) found that self-efficacy was related to a greater use of condoms and fewer sexual partners. However, perceptions of vulnerability were related to greater use of condoms, but also higher number of sexual partners.

Taken together, the above results suggest that PMT is a useful framework for understanding HIV-related protective behavior. Self-efficacy emerges as the most important predictor of such behavior, with response efficacy and severity also emerging as significant predictors in some studies. A conflicting pattern of results has been found with the vulnerability component. Similar conclusions have been reached by Farin (1994) in a meta-analysis of PMT and HIV-protective behavior, in which self-efficacy and response efficacy emerged as the best predictors of protective behavior. However, these two components were only able to explain 2.2% and 1.8% of the variance in such behavior. Severity was seen to be less important, and vulnerability had a conflicting pattern of results.

8.01.3.5.3 Commentary

Despite relatively few studies in the area, the above review highlights the potential utility of PMT as a framework for considering the social cognitive predictors of health protective behavior. However, there are a number of issues which future work needs to address.

First, some studies have reported a positive relationship between perceptions of vulnerability and protection motivation, while others have reported a negative relationship. Seydel et al. (1990) suggest that the negative relationship between vulnerability and intentions to engage in cancer-related preventive behavior in their study may be due to a "defensive avoidance" style of coping, in which perceptions of vulnerability to cancer may lead to feelings of anxiety which may inhibit adaptive responses and promote avoidance. However, it is more likely that the mixed pattern of results is due to measurement issues. As Weinstein and Nicolich (1993) argue, a negative correlation may be expected between perceptions of vulnerability and concurrent protective behavior given that one's current behavior may be used to make vulnerability judgments. In contrast, a positive correlation may be expected between perceptions of vulnerability and future protective behavior to the extent that perceptions of vulnerability motivates protective behavior. Considering behavioral intentions, individuals may feel vulnerable and therefore intend to engage in a protective behavior (i.e., positive correlation), or may feel vulnerable because they do not intend to engage in a protective behavior (i.e., negative correlation). Clearly, more consideration needs to be given to the measurement of perceptions of vulnerability and the potential use of conditional measures of risk.

Second, while PMT provides a framework for considering the social cognitive predictors of protective behavior, a number of researchers have commented on its lack of specification in terms of the nature of its components and the relationships between them (Bengel et al., 1996). For example, Rogers (1983) states that the response costs of the protective behavior need to be outweighed by perceptions of response efficacy and self-efficacy for protection motivation to be elicited. However, no guidance is given as to how these variables are to be measured and combined in order to predict protection motivation.

Overall, PMT identifies many of the social cognitive variables which are important predictors of health behavior. It shares a number of similarities with the HBM (i.e., measures of perceived susceptibility, severity, benefits, and barriers) although it also includes self-efficacy, which has been found to be one of the most powerful explanatory constructs in relation to health behavior (Schwarzer & Fuchs, 1996), and a measure of behavioral intention, which is seen to mediate the influence of threat appraisal and coping appraisal. It is also important for providing a synthesis between social cognitive approaches and coping models as outlined by Lazarus and Launier (1978). However, to date there have been relatively few longitudinal tests of PMT in relation to health behavior. Such studies should help clarify some of the issues raised above.

8.01.3.6 Self-efficacy

8.01.3.6.1 Model description

Self-efficacy is one of the most powerful predictors of health behavior (K. A. Wallston, 1992). It has its origins in Bandura's (1977) social cognitive theory which states that behavior is a function of both incentives (i.e., reinforcements) and expectancies. Three kinds of expectancies can be identified, these being situation-outcome expectancies which refer to beliefs about how events are connected, outcome expectancies which refer to beliefs about the consequences of performing a behavior, and self-efficacy expectancies which refer to beliefs about one's ability to perform the behavior. Thus in order to perform a health behavior, individuals must value their health (i.e., incentive), believe that their current lifestyle poses a threat to their health (i.e., situation-outcome expectancy), believe that adopting the new behavior will reduce the threat to their health (i.e., outcome expectancy) and believe that they are capable of performing the behavior (i.e., self-efficacy expectancy). While all these beliefs are seen to be important in the initiation and maintenance of health behavior, self-efficacy expectancies are seen to be the most important. Individuals with strong self-efficacy beliefs are believed to develop stronger intentions to act, to expend more effort to achieve their goals, and to persist longer in the face of barriers and impediments (Bandura, 1991).

Self-efficacy beliefs are therefore believed to play a crucial role in the determination of health behavior. According to Bandura (1977, 1982), such beliefs can be conceptualized and measured in terms of three parameters; magnitude, strength, and generality. The first parameter refers to the level of difficulty of the behavior. Individuals with low-level expectations feel capable of performing only very simple behaviors, whereas individuals with high-level expectations feel capable of performing even the most difficult of behaviors. In this way it is possible to assess individuals' expectations about their level, or magnitude, of performance. The second parameter refers to individuals' confidence that they could perform a specific behavior, while the third parameter refers to the generality of expectations across situations or domains. The measurement of self-efficacy usually focuses on the strength of the self-efficacy expectation (e.g., "I am confident that I can refrain from smoking"), although it will often incorporate the magnitude of expectation (e.g., "I am confident that I can refrain from smoking, even if someone offers me a cigarette").

8.01.3.6.2 Review of research

The self-efficacy construct has been successfully applied to the prediction of a range of health behaviors (see Bandura, 1991; O'Leary, 1985; Schwarzer & Fuchs, 1996). One of the main areas of application has been in relation to smoking cessation (Condiotte & Lichtenstein, 1981; Colletti, Supnick, & Payne, 1985; Kavanagh, Piere, Lo, & Shelley, 1993). These studies have found self-efficacy to be a consistent predictor of smoking cessation. For example, Condiotte and Lichtenstein (1981) found that post-treatment self-efficacy beliefs were predictive of both the probability of relapse and the amount of time before relapse. In addition, a close correspondence was noted between self-efficacy beliefs for a range of specific tempting situations (e.g., after a meal, when drinking coffee) and the actual situation in which the relapse occurred. The results therefore indicate that self-efficacy is important not only in predicting the likely success of smokers who are trying to quit, but also the situations in which they are most likely to relapse.

Self-efficacy has also been related to AIDS risk-reducing behaviors, such as condom use (Basen-Engquist & Parcel, 1992; Boyd & Wandersman, 1991; Kok, de Vries, Mudde, & Strecher, 1991; Morrison, Gillmore, & Baker, 1995). While the majority of studies examining the relationship between self-efficacy and AIDS risk-reducing behaviors have reported significant results, a few studies have failed to do so (Boyd & Wandersman, 1991; Morrison et al., 1995). Considering exercise behavior, self-efficacy has been found to be an important predictor of both intentions to engage in regular exercise and actual exercise behavior (Desharnais, Bouillon, & Godin, 1986; McAuley, 1993; Sallis, Howell, Hofsteffer, & Barrington, 1992). Finally, self-efficacy has also been related to dieting and weight control (Bernier & Avard, 1986; Hofstetter, Sallis, & Howell, 1990; Jeffrey et al., 1984). For example, Jeffrey et al. examined the relationship between self-efficacy and weight loss following participation in a behavioral treatment program over a two-year period. Making a distinction between "emotional" self-efficacy (i.e., confidence in one's ability to refrain from eating during various emotional states) and "situational" self-efficacy (i.e., confidence in one's ability to refrain from eating in various situations), they found pre-treatment measures of both types of self-efficacy to be predictive of weight loss at one and two years. However, post-treatment measures of self-efficacy were not so powerful with only "situational" self-efficacy predictive of weight loss at one year.

8.01.3.6.3 Commentary

The self-efficacy construct has been found to be one of the most important predictors of health behavior (K. A. Wallston, 1992). However, there are a number of issues which future work needs to address. First, the relationship between outcome and self-efficacy expectancies has been a source of some debate (Corcorcan, 1991; Kirsch, 1986, Maddux, 1993). As Schwarzer (1992) argues, there may be a temporal and causal order among the two types of expectancy beliefs inasmuch as individuals are unlikely to consider their ability to perform a behavior before first considering the efficacy of the behavior. Bandura (1991) argues that the effect of outcome expectancies on intentions and behavior are partly governed by self-efficacy expectancies; even if outcome expectancy is high, performance of a behavior is unlikely if self-efficacy is low. As a result, when self-efficacy is partialed out, any relationship between outcome expectancy and behavior should disappear. However, some research has indicated that outcome and self-efficacy expectancies can be independent predictors of intentions and behavior (Maddux, 1993).

Second, the role of incentives, or outcome values, has tended to be overlooked in research with the self-efficacy construct. This is despite the fact that a large body of research in expectancy value theory has found outcome value to be an important predictor (Kirsch, 1986; McCelland, 1985). Unfortunately, those studies which have considered the role of outcome and self-efficacy expectancies in conjunction with incentives or outcome values have produced mixed results (Maddux, Norton, & Stoltenberg, 1986; Manning & Wright; 1983).

Third, there is some disagreement over whether it is appropriate to consider generalized self-efficacy expectancies. According to Bandura's (1977) original conceptualization, self-efficacy beliefs should focus on specific behaviors in specific situations. Self-efficacy is not seen to be a personality trait as self-efficacy beliefs can be seen to vary across behaviors and situations, although self-efficacy beliefs may generalize to other behaviors and situations to the extent that the new behaviors require similar skills and the new situations have similar features (Bandura, 1986). Nevertheless, Schwarzer and Fuchs (1996) have argued that self-efficacy can be viewed as a generalized trait reflecting a personal resource factor, pointing to studies which have successfully employed generalized measures of self-efficacy to predict behavior (Mittag & Schwarzer, 1993; Snyder et al., 1991; K. A. Wallston, 1992). Generalized self-efficacy may be closely related to dispositional optimism (Scheier & Carver, 1992), although on an empirical level Schwarzer (1994) found a correlation of only 0.60 between dispositional optimism and generalized self-efficacy.

In conclusion, self-efficacy has been found to be one of the most powerful and consistent predictors of health behavior. For this reason alone, it is not surprising that it has been incorporated into a number of the main social cognition models of health behavior; for example, Rogers' (1983) PMT and Ajzen's (1991) TPB. In addition, Rosenstock, Strecher, and Becker (1988) have called for the inclusion of self-efficacy in the HBM. It is likely that self-efficacy will continue to attract considerable interest and continue to be a key predictor of health behavior.

8.01.4 ENCOURAGING THE ADOPTION OF HEALTH BEHAVIORS

8.01.4.1 Intervention Studies

The models presented earlier in this chapter outline some of the key social cognitive determinants of health behavior. In this section we consider the use of these models in the design of interventions to encourage new health behaviors. As Fishbein (1993) has argued, the ultimate test of the utility of these models lies in their ability to inform the design of effective interventions. To the extent that these models outline the key social cognitive determinants of health behavior, interventions which target these variables should lead to associated changes in behavior. However, to date there have been relatively few theoretically driven interventions. As a result there is still a need for more tests of these models "in action" (Fishbein, 1993).

Brawley (1993) argues that we need to take account of the practicality of employing SCMs when designing interventions. In short, a model which offers a high level of practicality must be shown to have predictive utility, to describe the relationships between key constructs, to offer guidelines for the assessment of these constructs, to allow the translation of these constructs into operational manipulations, and to provide the basis for detecting the reasons why an intervention succeeds or fails. The SCMs considered here can be been seen to have a high level of practicality and therefore should provide a good framework for the design of effective interventions.

One model which has been used widely to design interventions is the PMT. A good example of the use of PMT in this respect is provided by Wurtele and Maddux (1987) in their study on exercise intentions and behavior. In this study essays recommending beginning a regular exercise program were presented to a sample of nonexercising female undergraduates. The essays were designed so that each of the PMT's main components (i.e., severity, vulnerability, response-efficacy, and self-efficacy) were independently manipulated, resulting in a 2 × 2 × 2 × 2 between-subjects factorial design with two levels (present vs. absent) of each factor. For example, the severity message emphasized the seriousness of the threat of a sedentary lifestyle by vividly describing the negative effects of a heart attack (e.g., "Nauseated, the victim vomits; pink foam comes out of the mouth. The face turns ashen grey, sweat rolls down the face . . ."). After reading an essay, subjects completed a questionnaire containing measures of the main components of PMT and were followed up two weeks later to chart any changes in exercise behavior.

Manipulation checks revealed that each of the messages successfully manipulated their corresponding component from PMT, as is the case in most PMT intervention studies. Of more interest was the effect of the messages on protection motivation as measured by behavioral intentions to start a regular exercise program. The results showed that only the vulnerability and self-efficacy messages had a significant effect on behavioral intentions, although a three-way interaction between vulnerability, response efficacy, and self-efficacy was also found. In relation to changes in exercise behavior over the two-week follow-up period, a significant interaction was found between severity and self-efficacy, such that the self-efficacy message only had a significant effect when the severity message was absent.

Overall, studies which have used PMT to design interventions have shown that self-efficacy is the most powerful component that can be manipulated in persuasive messages (Boer & Seydel, 1996). In addition, manipulating response efficacy has been found to have a significant effect on intentions in a majority of studies. These two variables have been shown to influence intentions to engage in a range of health behaviors including exercise (Stanley & Maddux, 1986), quit smoking (Maddux & Rogers, 1983), dietary intake (Wurtele, 1988), and breast self-examination (Rippetoe & Rogers, 1987). Manipulating perceptions of vulnerability has been found to influence intentions in other studies (Maddux & Rogers, 1983; Wurtele & Maddux, 1987), while manipulating perceptions of severity has not been found to have an influence on behavioral intentions. However, many PMT intervention studies have combined the vulnerability and severity components so that the potential threat of a maladaptive behavior is emphasized. This has been found to have a significant effect on intentions in relation to alcohol use (Stainback & Roger, 1983), dental flossing (K. H. Beck & Lund, 1981), dietary behavior (Wurtele, 1988), information seeking (Brouwers & Sorrentino, 1993), and breast self-examination (Rippetoe & Rogers, 1987).

Some studies have focused more specifically on enhancing feelings of self-efficacy as a means for encouraging health behavior change. As Bandura (1986) outlines, there are four main sources of self-efficacy, each of which could be addressed in interventions. First, individuals can develop feelings of self-efficacy from personal mastery experience. For example, it may be possible to split a behavior into various subgoals, such that the easiest subgoals are achieved before more difficult tasks are attempted. Second, individuals may develop feelings of self-efficacy through observing other people succeed on a task (i.e., vicarious experience). Third, it is possible to use standard persuasive techniques to try to instil feelings of self-efficacy. Finally, one's physiological state may be used as a source of information, such that high levels of arousal or anxiety may indicate to the individual that he or she is not capable of performing a given action. As a result, relaxation techniques may be employed to help maintain feelings of self-efficacy.

Each of these techniques have been used in intervention studies to try to enhance feelings of self-efficacy. Maibach, Flora, and Nass (1991) report the results of a year-long community health campaign to encourage the adoption of health behaviors. The campaign materials were all designed to reflect the main principles of Bandura's (1986) social cognitive theory and used a number of strategies for enhancing feelings of self-efficacy and encouraging behavior change attempts. These included encouraging participants to set behavior change goals, using community members who had successfully changed their behavior as role models, using health experts to give advice about behavior change and focusing on the skills needed to support behavior change. The campaign was found to successfully increase feelings of self-efficacy which, in turn, were related to the adoption of new health behaviors.

A number of interventions have focused on more situation-specific feelings of self-efficacy. Stevens and Hollis (1989) designed an intervention to help smokers quit smoking which built on the results of earlier research which had shown that situation-specific ratings of self-efficacy were predictive of the circumstances in which relapses occurred (Condiotte & Lichtenstein, 1981). Abstinent smokers have identified potential relapse situations in which they perceived low levels of self-efficacy and then developed and rehearsed appropriate coping strategies over three weekly meetings. This intervention led to a greater abstinence rate at one year than both a discussion-only intervention and a no-treatment control. Other studies which have attempted to improve behavioral skills to enhance feelings of self-efficacy have produced positive results in relation to alcohol use (Baer et al., 1992) and dental hygiene (McCaul, Glasgow, & O'Neil, 1992).

Few studies have attempted to use the TRA/TPB as a framework for developing interventions, despite quite clear guidelines outlined by Ajzen and Fishbein (1980). In fact, van den Putte (1993) reports a mere five studies which have followed such an approach, with only limited evidence for success compared to approaches not based upon the model. For example, Brubaker and Fowler (1990) examined the effect of persuasive messages upon men's intentions to perform testicular self-examination. A persuasive message based on the theory of reasoned action was found to increase intentions to perform testicular self-examination compared to a no-message control, but was no more effective than a knowledge-only message. More recently, Parker, Manstead, and Stradling (1996) have developed intervention videos based on the TPB to discourage speeding in residential areas by car drivers. The results showed that the normative belief video had a significant effect on a postintervention measure of normative beliefs, while the behavioral belief video had no effect on behavioral beliefs, and the perceived behavioral control video had a negative effect on perceptions of control. Overall, the videos had no effect on subjects' expectations of speeding in residential areas over the next year.

Finally, there is some evidence that tailoring interventions to fit in with individuals' existing belief orientations may lead to more effective interventions. Chambliss and Murray (1979a) devised a weight control program in which participants were given placebo medication to help control their metabolism. After two weeks participants in one group were debriefed about the placebo medication and encouraged to attribute any weight loss to their own efforts over the previous two weeks. Participants in a second group were given further information about the efficacy of the medication and encouraged to attribute any weight loss to the medication. At two-week follow-up, a significant interaction was found between the giving of information and participants' preprogram locus of control orientation, such that "internals" lost more weight than "externals" in the self-efficacy information group, while the opposite pattern of results was found for the drug information group. Similar results have been reported by Chambliss and Murray (1979b) in relation to smoking cessation. These results led to further work exploring the match between the control orientation of the intervention and participants' existing health locus of control beliefs. For example, Quadrel and Lau (1989) found an interaction between health locus of control beliefs and the control orientation of a message to encourage breast self-examination among female students. In particular, those females with strong internal health locus of control beliefs who received a message in a "control" frame were more likely to perform breast self-examination at follow-up, although this effect was reversed if a neutral reminder was sent. Further evidence for a "matching hypothesis" has been provided in relation to weight reduction (B. S. Wallston, Wallston, Kaplan, & Maides, 1976) and smoking cessation (Best, 1975).

Despite offering a high level of practicality, there have been relatively few studies testing SCMs "in action." As the above review shows, practical applications of these models have met with some success and suggest that health behavior change interventions may have a lot to gain from using these models as a guiding framework. As Lewin (1951) concludes, "there is nothing so practical as a good theory" (p. 169).

8.01.5 LIMITATIONS AND EXTENSIONS OF EXISTING MODELS

8.01.5.1 Limitations of Current Models

The SCMs described above represent one widely used approach to understanding health behaviors. Here we provide a critique of this approach to understanding health behavior and outline ways in which research might develop through consideration of additional theoretical constructs, the processes by which cognitions influence behavior, stage models of behavior change, potential integrations, and future directions for work in this area.

There are several advantages of using social cognition models in health psychology (Conner, 1993; Conner & Norman, 1996b). First, they provide a clear theoretical background to research, guiding the selection of variables to measure, the procedure for developing reliable and valid measures, and how these variables are combined in order to predict health behaviors and outcomes. Second, to the extent that the models identify the important variables in predicting health outcomes and behaviors, they enable us to develop effective behavioral interventions. Third, the models provide us with a description of the cognitive processes determining individuals' motivation to perform different behaviors.

There are parallel disadvantages in too exclusive a focus upon social cognition models as the way to understand health behaviors. First, in providing such an explicit general theoretical framework, these models may lead us to neglect variables (cognitive and noncognitive) potentially important in understanding a particular health behavior or outcome. For example, the decision to use a condom may be a function of cognitions, emotional reactions, and also a complex interaction between the individuals involved. Social cognition models on their own are unlikely to provide considerable predictive power in these situations. In addition, SCMs are open to extension when empirically and theoretically justified (Fishbein, 1993).

Second, while such models provide us with targets for interventions to produce behavior change, they do not specify how such cognitions are best changed. Effective interventions need to consider both the targets (e.g., cognitions) and the persuasion process itself. This process of persuasion is described by other models of social cognitive processes (e.g., the elaboration likelihood model: Petty & Cacioppo, 1986; the systematic-heuristic model: Chaiken, Lieberman, & Eagly, 1989). In addition, applications of SCMs should not lead to neglect of alternatives to persuasion in producing behavior change such as extrinsic changes to the rewards and costs of a given behavior. For example, increased taxation and legal restrictions can be effective in producing change in health behaviors either in isolation or in tandem with persuasion.

Third, although SCMs have furthered our understanding of motivational processes and their influence upon behavior, they have neglected other aspects of behavior change. For example, few of the models consider volitional processes beyond attempting to explain intentions (Bagozzi, 1993; Gollwitzer, 1990). However, many individuals who intend to change fail to do so. Hence, we need to consider the other important volitional processes associated with attempts to change and maintain behavior change (see Norman & Conner, 1996a; Schwarzer & Fuchs, 1996).

8.01.5.2 Additional Theoretical Constructs

While the social cognition models outlined here provide an important framework for considering the social psychological determinants of health behavior, it is clear that in some instances they only account for a modest amount of the variance in health behavior. For example, Sheppard et al. (1988) noted that about 10% of studies they reviewed reported correlations between behavioral intentions and behavior below 0.2. This suggests that key variables have failed to be included in these models. We review here the most promising of such variables appearing in the literature: measures of norms, anticipated affective reactions, self-identity, and past behavior.

A number of researchers have argued that further attention needs to be paid to the concept of normative influences (e.g., Cialdini, Reno & Kallgren, 1990; Conner, Martin, Silverdale, & Grogan, 1996). Of the major SCMs, only the TPB incorporates perceived social pressures to perform a behavior as a predictor of intentions. Based upon social identification theory, Terry and Hogg (1996) suggest that such (injunctive) normative measures might be more predictive of behavior if they employed a measure of group identification rather than motivation to comply (e.g., I identify with my friends with regard to smoking). Similarly, Gibbons and Gerrard (1995, 1997) have noted the need to consider social comparison processes and how the social image or prototype of the person who performs a particular behavior influences the performance of various health behaviors (particularly among young people). Other researchers have suggested other forms of normative influence we might consider. These include descriptive norms and personal or moral norms. Descriptive norms are perceptions of the behavior of salient others. For example, Jane's eating behavior may be influenced not only by her perceptions of what others think she should eat, but also perceptions of what they actually do eat. Several studies have reported that perceptions of others' behavior contributed to the prediction of intentions independently of perceived injunctive norms (e.g., Conner et al., 1996; De Vries, Backbier, Kok, & Dijkstra, 1995; Grube, Morgan, & McGee, 1986). Personal, or moral, norms are the individual's perception of the moral correctness or incorrectness of performing a behavior (Ajzen, 1991; Sparks, 1994) and take account of, "... personal feelings of ... responsibility to perform, or refuse to perform, a certain behavior" (Ajzen, 1991, p. 199). Moral norms should have an important influence on the performance of those behaviors with a moral or ethical dimension (L. Beck & Ajzen, 1991; Gorsuch & Ortberg, 1983; Kurland, 1995). A number of studies have found measures of moral norms to be predictive of blood donating behavior (Pomazal & Jaccard, 1976; Zuckerman & Reiss, 1978) as well as intentions to donate organs (Schwartz & Tessler, 1972), eat genetically produced food (Sparks, Shepherd, & Frewer, 1995), buy milk (Raats, 1992), use condoms (Nucifora et al., 1993), and commit driving violations (Parker, Manstead, & Stradling, 1995).

Anticipated affective reactions to the performance or nonperformance of a behavior may also be an important determinant of behavior (Triandis, 1977; Van der Pligt & de Vries, 1998), especially in situations where the consequences of the behavior are unpleasant or negatively affectively laden. In the 1990s research has focused on the influence of anticipated regret (Parker et al., 1995; R. Richard & van der Pligt, 1991; Richard, Van der Pligt, & de Vries, 1995, 1996a, 1996b). It is argued that if individuals anticipate feeling regret after performing a behavior then they will be unlikely to perform the behavior. Richard et al. (1995, 1996a) investigated the role of anticipated regret in relation to condom use among adolescents and found such feelings to be an important predictor of intentions. Richard et al. (1996b) examined the influence of anticipated regret on subsequent behavior. Participants in their study were asked to either focus on their anticipated feelings following safe and unsafe sexual behavior or on their present feelings about these behaviors. At follow-up, participants in the anticipated feelings condition were more likely to have used condoms in casual sexual encounters in the intervening five months. The effects of anticipated affective reactions have been confirmed in studies of driving (Parker, Manstead, Stradling, Reason, & Baxter, 1992) and consumer behavior (Simonson, 1992). However, in terms of developing social cognition models of health behavior, it is possible to argue that anticipated affective reactions may be incorporated into constructs that focus on the consequences of behavior (e.g., behavioral beliefs in the TPB; see Van der Pligt & de Vries, 1998).

The concept of self-identity has also been suggested as a predictor of behavior (Biddle, Bank, & Slavings, 1987; Charng, Piliavin, & Callero, 1988). For example, the extent to which individuals think of themselves as "healthy eaters" should predict their dietary intentions and behavior. In support, Sparks and Shepherd (1992) found that respondents who thought of themselves as "green consumers" had stronger intentions to consume organic vegetables. Sparks (1994) noted that self-identity may simply be a proxy for past behavior, although Sparks and Shepherd (1992) found that the relationship between self-identity and future intentions remained when past consumption of organic vegetables was controlled for. Self-identity as someone who is concerned about the health consequences of one's diet has also been related to intentions to reduce fat consumption (Sparks, Shepherd, Wieringa, & Zimmermanns, 1995), although in an earlier study Sparks, Shepherd, Wieringa, and Zimmermanns (1994) failed to find an independent effect for self-identity. Role identity (regarded as synonymous with self-identity) was measured by Theodorakis (1994) and found to be a significant predictor of exercise behavior. Future work needs to assess the influence of self-identity across of range of behaviors as it may be the case that self-identity is only important in a restricted range of situations.

The influence of past on current behavior in SCMs has attracted much attention. It is argued that many health behaviors are determined by one's previous behavior rather than cognitions. The argument is based on the results of a number of studies showing past behavior to be the best predictor of future behavior. For example, Mullen, Hersey, and Iverson (1987) found initial behavior to be the strongest predictor of the consumption of sweet and fried foods, smoking, and exercise over an eight-month period. Similar results have been reported in relation to drug use (Bentler & Speckart, 1979; Huba, Wingard, & Bentler, 1981), exercise (Godin, Valois, & Lepage, 1993; Norman & Smith, 1995; Valois, Desharnais, & Godin, 1988), breast self-examination (Hodgkins & Orbell, 1998), attendance at health checks (Norman & Conner, 1993, 1996b) and seat belt use (Sutton & Hallett, 1989). Such results have led to calls for past behavior to be considered as an independent predictor of future behavior (Bentler & Speckart, 1979; Fredricks & Dossett, 1983). However, there are problems with this view. Ajzen (1988) argues that the effects of past behavior on future behavior should be mediated by the variables included in social cognition models; past behavior shapes individuals' beliefs about the behavior in question, and it is these cognitions that determine subsequent behavior. When past behavior is found to have a direct effect on future behavior it is because key social cognitive variables have not been considered (Ajzen, 1991).

There has also been focus on the concept of habit (i.e., behaving in a way you have acted before without thinking about it). Eagly and Chaiken (1993) review numerous studies where the addition of habit has added to the prediction of future behavior over and above the influence of variables such as intention, attitude, and subjective norm. Despite this evidence, few SCMs incorporate a measure of habit. A notable exception is Triandis (1977) who argues that it is possible to make a distinction between habitual and intentional behaviors. He argues that novel behaviors will be primarily determined by intention, while repeated behaviors will be primarily determined by habit. Ronis, Yates, and Kirscht (1989) make a similar distinction between habits and decisions, arguing that the performance of repeated behavior is determined by habit rather than social cognitive variables. For example, Dishman (1982) distinguished between the initiation and maintenance of behavior in relation to clinical exercise programs and found that only the initiation of exercise behavior was predicted by social cognitive variables. Sutton (1994) has proposed a further distinction between habits and routines. He argues that many health behaviors commonly considered habitual may be more appropriately considered routines. Sutton (1994) describes a routine as a sequence of behaviors which is repeated on a regular basis. However, what distinguishes them from habits is their need to be supported by self-reminders. It may be possible therefore to make the distinction between occasions when the influence of past behavior is mediated by social cognitive variables and those occasions when it is seen to have a direct influence via habitual responses. In particular, future work should develop measures of habit and routine that are discriminable from frequency of past behavior and outline the processes through which habit and routine determine behavior.

8.01.5.3 Processes by which Cognitions Influence Behavior

One important implication of Ronis et al.'s (1989) distinction between habits and decisions is the suggestion that social cognition models may only predict health behavior under certain conditions. This issue has been addressed by Fazio (1990) in the development of the MODE model of attitude–behavior relationships. He suggests that attitudes (and presumably other cognitions) influence behavior via two distinct processes: a deliberative (or controlled) process and a spontaneous process. Most social cognition models can be labeled as deliberative processing models as they assume that behavior results from a controlled process of conscious deliberation. However, Fazio (1990) argues that individuals may only make a behavioral decision in such a manner when they have the opportunity and motivation to do so. Under other conditions, attitudes which are highly accessible in memory may determine behavior in a spontaneous fashion (Fazio, Powell, & Williams, 1989). When the spontaneous process is operating, an attitude may be automatically activated from memory following the presentation of relevant cues, with the likelihood of activation determined by the accessibility of the attitude. Once activated, the attitude shapes the perception of the attitude object in an automatic, attitude-congruent, fashion. For example, if a positive attitude is activated then this will lead the individual to attend to and notice the positive qualities of the attitude object. This automatic process of selective perception will therefore shape the individual's definition of the event, and thus determine behavior. If the event is defined on the basis of positive perceptions of the attitude object, for example, then approach behaviors will follow. In addition, it is argued that normative guidelines (e.g., social norms or rules) may also influence the definition of the event and thus may help to determine behavior in some situations.

One important feature of the spontaneous processing model is that it outlines one way in which social cognitive variables (i.e., highly accessible attitudes) may determine behavior without systematic deliberation. To date, there has been little research on Fazio's model, although it has been successfully shown that the accessibility of relevant attitudes influences the strength of the relationship between attitudes and behavior (Fazio & Williams, 1986) and that highly accessible attitudes can lead to selective perception (Houston & Fazio, 1989; Fazio & Williams, 1986). Both findings are consistent with the spontaneous processing model. This above work has important implications for SCMs and health behaviors. The SCMs outlined here are deliberative processing models inasmuch as they focus on the conscious processing of information and fail to consider spontaneous or automatic influences on behavior. Hence, current SCMs may provide only a partial account of the social cognitive determinants of behavior, that is, they may only be applicable in situations where the individual has the ability and motivation to engage in deliberative processing of information (Conner, 1993). For many behavioral decisions, simplified or spontaneous decision-making rules may be employed instead (Norman & Conner, 1993). Fazio's (1990) spontaneous model has considerable potential in helping to provide a full account of the cognitive influences on behavior. However, it is clear that most of the empirical work to date has focused on issues surrounding the activation of attitudes and their influence on perception; later components of the model have received less attention.

8.01.5.4 Stage Models of Health Behavior

A number of researchers have suggested that there may be qualitatively different stages in the initiation and maintenance of health behavior, and that to obtain a full understanding of the determinants of health behavior it is necessary to conduct a detailed analysis of the nature of these stages. From a social cognitive perspective, an important implication of this position is that different cognitions may be important at different stages in promoting health behavior.

One of the first stage models was put forward by Prochaska and DiClemente (1984) in their transtheoretical model of change (TTM). Their model has been widely applied to analyze the process of change in alcoholism treatment (DiClemente & Hughes, 1990), smoking cessation (DiClemente et al., 1991), head injury rehabilitation (Lam, McMahon, Priddy, & Gehred-Schutlz, 1988), and psychotherapy (McConnaughly, DiClemente, Prochaska, & Velicer, 1989). In its most recent form, DiClemente et al. (1991) identify five stages of change: precontemplation, contemplation, preparation, action, and maintenance. Individuals are seen to progress through each stage to achieve successful maintenance of a new behavior. Taking the example of smoking cessation, it is argued that in the precontemplation stage smokers are unaware that their behavior constitutes a problem and have no intention to quit. In the contemplation stage, smokers start to think about changing their behavior, but are not committed to try to quit. In the preparation stage, the smoker has an intention to quit and starts to make plans about how to quit. The action stage is characterized by active attempts to quit, and after six months of successful abstinence the individual moves into the maintenance stage characterized by attempts to prevent relapse and to consolidate the newly acquired nonsmoking status. Whilst relative widely applied, the evidence in support of the model and the different stages is at present relatively weak (see Weinstein, Rothman, & Sutton, in press).

Heckhausen (1991) has similarly identified phases in the initiation and maintenance of behavior change; these being the predecisional, postdecisional, actional, and evaluative phases, which follow a similar progressive sequence as that outlined by Prochaska and DiClemente (1984). It is further suggested that different types of cognitions are important in each of these phases. So in the predecisional phase, cognitions about the desirability and feasibility of the behavior are believed to be important determinants of a desire to perform the behavior in question. This phase ends with the formation of an intention to change. In contrast, the decisional phase focuses on the development of plans and ends with the successful initiation of the behavior. In the actional phase the individual focuses on effectively achieving performance of the behavior and ends with the conlusion of the behavior. In the final, evaluative phase the individual compares achieved outcomes with initial goals in order to regulate and maintain behavior. While this four phase model of behavior was not developed for the prediction of health behavior, the potential for its application is clear (see Gollwitzer, 1993). Other stage models have been developed including the health action process approach (Schwarzer, 1992; Schwarzer & Fuchs, 1996), the precaution-adoption process (Weinstein, 1988, Weinstein & Sandman, 1992), and goal setting theory (Bagozzi, 1992, 1993; Bagozzi & Edwards, 1998).

There are two important themes in each of the stage models outlined above. First, they emphasize a temporal perspective with different stages of behavior change. While the models postulate different numbers of stages, they all follow the same pattern from a precontemplation stage through a motivation stage to the initiation and maintenance of behavior. The important point is that these models are dynamic in nature; people move from one stage to another over time. Second, these stage models imply that different cognitions are important at different stages (Sandman & Weinstein, 1993). For example, in the earlier stages information may be processed about the costs and benefits of performing a behavior, while in the later stages cognitions become more focused on the development of plans of action to initiate and support the maintenance of a behavior. This earlier motivational phase is assumed to end with the formation of an intention and only when the level of motivation or intention reaches a particular level is the individual assumed to be likely to move on to later stages.

The main SCMs of health behavior are primarily concerned with people's motivations to perform a health behavior and, as such, provide strong predictions of behavioral intentions (i.e., the end of a motivational stage). Ajzen (1991), for example, reports an average multiple correlation of 0.71 between variables in the TPB and behavioral intention. However, intentions do not always lead to corresponding actions. Studies examining the intention–behavior relationship have reported a wide range of correlations. For example, Sheppard et al. (1988) reported intention–behavior correlations ranging from 0.10 to 0.94. Clearly, many people who intend to perform a behavior fail to do so. However, the SCMs considered do not address the issue of translating intentions into action. They can be conceptualized as static models that stop at the formation of an intention without distinguishing between intenders who become actors and those who do not. As Bagozzi (1993) argues, the variables outlined in the main social cognition models are necessary but not sufficient determinants of behavior. Clearly, a detailed analysis of the social cognitive variables important in translating intentions into action is required to provide a full account of the determinants of health behavior.

Relatively little detailed attention has focused on the cognitive processes underlying the successful implementation of intentions. The main social cognition models contain few measures that account for the intention–behavior gap (Abraham & Sheeran, 1993). The TPB attempts to do this by proposing a direct link between perceived behavioral control and behavior. Thus, people's perceptions about the amount of control they have over a behavior influence the likely performance of behavior independently of their intentions, although an analysis of the volitional processes underlying performance of a health behavior is required, and a number of researchers have focused attention on this issue (e.g., Kuhl, 1985; Schwarzer, 1992; Weinstein, 1988). Here we focus on Gollwitzer's (1993) work on implementation intentions and Bagozzi's (1992) model of goal achievement to highlight the social cognitive variables important in the initiation and maintenance of behavior.

Gollwitzer (1993) made the distinction between goal intentions and implementation intentions. While the former are concerned with intentions to perform a behavior or achieve a goal (i.e., "I intend to achieve x"), the latter are concerned with plans as to when, where, and how the goal intention is to be translated into behavior (i.e., "I intend to initiate the goal-directed behavior x when situation y is encountered"). Goal intentions are most like the intention construct in the TPB, although in the TPB such intentions usually refer to actions or behaviors rather than goals. The important point about implementation intentions is that they commit the individual to a specific course of action when certain environmental conditions are met; in so doing they help translate goal intentions into action. Gollwitzer (1993) argues that by making implementation intentions individuals pass over control to the environment. The environment acts as a cue to action, such that when certain conditions are met, the performance of the intended behavior follows. These ideas have similarities with Weinstein's (1988) "messy desk" analogy, whereby people may have intentions to achieve a number of goals (i.e., "projects") which get "lost" on the "messy desk." Which project is actually worked upon is determined by environmental factors in a similar way as outlined by Gollwitzer (1993).

Gollwitzer (1993, 1996) has compiled a range of experimental evidence to support the view that the making of implementation intentions can aid the performance of intended behavior. To date, the only application of implementation intentions to the prediction of health behavior is a study by Orbell, Hodgkins, and Sheeran (1997) on breast self-examination. At the end of a questionnaire about breast self-examination, half the women were asked to indicate when and where in the next month they intended to perform breast self-examination. A one month follow-up found that 64% of these women had performed breast self-examination that month compared with only 16% of women who had not made an implementation intention, despite no difference in goal intentions. In addition, everyone in the implementation condition who actually performed the behavior reported doing so in response to the environmental cue in the implementation intention and not in response to any other environmental cue. This suggests that the making of an implementation intention can significantly increase the performance of a behavior. In a study on exercise behavior, Kendzierski (1990) found that respondents were more likely to implement their intentions to exercise when they had engaged in some prior planning. Further work needs to establish the utility of implementation intentions in predicting health behavior. However, initial findings are encouraging and suggest that those who make such plans of action are more likely to initiate and maintain behavior.

The work of Gollwitzer (1993) is important in that it identifies one way in which goal intentions may be translated into behavior. A similar but more comprehensive approach has been put forward by Bagozzi (Bagozzi, 1992, 1993; Bagozzi & Edwards, 1998; Bagozzi & Warshaw, 1990) in his model of goal achievement. He focuses on goal-directed behavior and argues that to initiate behavior individuals need to form an "intention to try" to achieve their desired goal. Once an intention to try has been formed, the individual focuses on the means, or instrumental acts, by which to attempt to achieve the desired goal. Considering the example of weight loss, a number of instrumental acts can be identified, including restricting between-meal foods, reducing overall calorie consumption, avoidance of high calorie foods, exercise, and so on. Bagozzi (1993) argues that for each of these instrumental acts, three appraisal tasks are performed. First, the individual considers the extent to which they are confident that they could perform the instrumental act (i.e., specific self-efficacies). Second, the likelihood that the instrumental act will help in achieving the desired goal is assessed (i.e., instrumental beliefs). Third, the individual considers an affective response towards the instrumental act (i.e., affect towards means). Once an individual initiates efforts to achieve a goal, there are a number of cognitive activities that support the successful initiation and maintenance of goal-directed behavior. First, the individual can develop plans in order to ensure that instrumental acts are performed. This involves identifying the situation or triggering conditions under which the instrumental act is performed (Bagozzi & Warshaw, 1990). This idea that certain environmental conditions may trigger behavior has a clear overlap with Gollwitzer's (1993) work on implementation intentions and Weinstein's (1988) "messy desk" analogy. One way in which plans are more likely to be acted upon is through the development of scripts or cognitive rehearsal, whereby the individuals imagine themselves performing the instrumental act (Anderson, 1983). Another is through the use of precommitting devices whereby the behavior is made more likely by precommitting oneself to it (e.g., avoiding eating butter at home by not having butter in the house). Bagozzi (1993) also proposes that ongoing behavior has to be monitored to ensure, for example, that the instrumental acts achieve their objectives. If any unforeseen impediments are encountered then these need to be taken into consideration and any future plans modified accordingly. These ideas overlap with Kuhl's (1985) theory of action control which identifies a number of processes by which individuals attempt to control their actions and achieve their goals. These processes may be particularly important in allowing individuals to overcome temptations to break their new behavior (see Loewenstein, 1996). Finally, goal-directed behavior is likely to be stronger and more persistent if the individual has a strong sense of commitment to the decision to try to achieve the goal and the means to achieve it.

8.01.5.5 Theoretical Integrations and Future Directions

The above research demonstrates some of the ways in which research into health behaviors based upon social cognitive approaches is developing. Here we outline possible directions for the future development of an integrative social cognition model of health behavior, outline some of the basic requirements for such a model, and indicate some fruitful avenues for future research.

It is clear that to fully explain health behavior it is necessary to develop a more dynamic model that examines different stages or phases in the contemplation, initiation, and maintenance of behavior. What is being proposed is an integration of current SCMs (such as the TPB) with stage models of health behavior (such as the TTM). Several authors have recommended such an integration (e.g., Courneya, Nigg, & Estabrooks, 1998; Godin, Desharnais, Valois, & Bradet, 1995; Marcus, Eaton, Rossi, & Harlow, 1994). Though the stage models considered in this chapter have suggested differing number of stages, it is likely that an integrative model should address at least four or five main stages: precontemplation, contemplation, planning, action, and maintenance (Norman & Conner, 1996a).

One implication of the identification of different stages is that different cognitive variables may be important in ensuring movement from one stage to the next. In the first stage, the individuals are not thinking about making a change to their behavior. However, this stage may be brought to an end by a range of cues to action, as outlined in the HBM, which may motivate the individual to start thinking about performing a health-related behavior. One such cue to action may be perceived threat (i.e., perceived susceptibility and perceived severity). While perceived susceptibility and perceived severity are seen to be important determinants of behavior in the HBM, research with these dimensions has tended to show that they are relatively weak predictors of behavior. However, as Schwarzer (1992) has argued, it may be more appropriate to consider these variables to have an indirect or more distal influence on behavior. Thus they may act as a cue to action, motivating the individual to start deliberating over performing a health-related behavior, and thus ensuring movement from the first to the second stage.

In the second stage, a decision-making or motivation stage, the individual is thinking about adopting a new behavior, and the stage ends when the individual forms an intention to perform the behavior. To date, most social cognition models have been primarily concerned with this stage. These models distinguish between three distinct determinants of individuals' intentions to perform a health behavior. First, are outcome expectancies, which focus on the perceived consequences of performing a behavior. These expectancies may also cover the notion of behavioral beliefs as considered in the TPB and include anticipated affective reactions. Second, are normative influences which are primarily tapped by the subjective norm and normative belief components of the TPB. This group of variables could also include descriptive norms, moral norms, and perceived social support. The third influence on individuals' intentions to perform a behavior is control beliefs (or self-efficacy expectancies) and may be based on a consideration of perceived barriers (HBM) and control beliefs (TPB). In the motivation stage, it is likely that other variables may have a more distal influence on behavioral intention via the variables outlined above. For example, health locus of control beliefs may help shape self-efficacy expectancies, self-identity and health values may influence the interpretation of the potential consequences of a behavior, and past behavior or experience may provide information which is used to determine the ease or difficulty of performing a behavior (i.e., self-efficacy).

Once a behavioral intention has been formed, it has to be translated into behavior. In the third stage, the individual is therefore concerned with planning; focusing on the specific actions or instrumental acts that need to be performed and the resources required to support them. Thus, a number of authors have highlighted the importance of action plans in this stage (Bagozzi & Warshaw, 1990; Schwarzer, 1992). Similarly, Gollwitzer (1993) focuses on implementation intentions which help ensure performance of the target behavior. Despite slight differences between definitions of these two concepts, both emphasize the need to construct fairly detailed plans of action in order to bridge the intention–behavior gap. As Schwarzer (1992) argues, self-efficacy may have an important role to play in the development and implementation of such plans, as might self-identity (Sparks & Shepherd, 1992) and a sense of commitment (Bagozzi, 1993). The planning stage is brought to an end when the individual initiates behavior.

In the fourth stage, the individual has to ensure that the behavior is successfully enacted. Various cognitive processes which are concerned with the monitoring and controlling of behavior may be important in this stage. Schwarzer (1992), for example, highlights the need for action control in which the behavior is re-evaluated against initial goals in order to regulate and maintain behavior (see also Bagozzi & Warshaw, 1990; Heckhausen, 1991). As with the development of action plans, self-efficacy, self-identity, and commitment may all be important variables in ensuring that behavior is maintained. In addition, Kuhl (1985) has argued that there may be individual differences in people's propensity to engage in monitoring activities that may account for why behavior is not always maintained. These monitoring activities help to ensure that the behavior is successfully completed. The same activities will be important in the fifth, maintenance stage for ongoing behaviors, where the individual is concerned with ensuring that the behavior is successfully repeated.

8.01.6 CONCLUSIONS

Health behaviors have been demonstrated to have important consequences for both the quality and length of life through influencing various disease outcomes. We have attempted to justify the interest in understanding health behaviors as a basis for attempting to change their occurrence in order to increase both length and quality of life. SCMs provide one approach to understanding health behavior in describing the important social cognitive variables underlying such behaviors. We believe that these models provide an important way of achieving these aims by providing a means for identifying useful targets for persuasion. It would seem that there is already sufficient literature to support the contention that important determinants of health behaviors are identified in these models. Further refinement and development of these models along the lines we have suggested and reviewed may lead to even better predictions of behavior and greater understanding of health behavior and how individuals may be encouraged to change.

However, persuasive messages targeted at relevant cognitions identified by SCMs may not be sufficient to produce the major behavior change necessary for health benefits to accrue. It may be that strategies which employ multiple level interventions which take account not only of the psychosocial factors influencing performance of the behavior (derived from SCMs) but also models of the process of persuasion of how people change and the context in which changes are made will be important (Glanz et al., 1990; Hockbaum & Lorig, 1992; Winett, 1985).

8.02.1 INTRODUCTION

All behavioral states and activities are underpinned by variations in physiological activity, and are associated with specific patterns of autonomic nervous system, neuroendocrine, and metabolic response. The relationship between emotional disturbances and physiological function has been recognized since the work of Sherrington, Cannon and their contemporaries was carried out nearly 100 years ago. One of the fundamental concepts underlying clinical health psychology is that psychosocial factors influence the etiology and maintenance of disease through perturbation of physiological functions. This chapter will evaluate the empirical evidence supporting this concept, and will outline the theoretical framework within which psychophysiological or psychobiological processes can best be understood.

The range of experimental and clinical research relevant to this topic is large, since it not only includes work on the regulation of peripheral bodily functions by the brain, but also the distinctive pathological processes implicated in individual medical disorders. The chapter begins with a discussion of the psychophysiological research framework, basic models of stress and coping, and methods of investigation and quantification. The nature and pattern of psychophysiological responses is then described, together with an outline of the psychosocial factors that influence the intensity and duration of these responses. Later sections of the chapter describe how the physiological responses elicited by psychosocial factors actually affect disease mechanisms and increase health risk.

In keeping with the remit of health psychology, the focus is on nonpsychiatric "medical" conditions and on peripheral rather than central nervous system psychophysiology. Thus the role of physiological factors in problems such as depression, panic, or hypochondriasis will not be discussed. This does not imply an endorsement of Cartesian dualism, or a belief that psychiatric and nonpsychiatric disorders are regulated by different processes. Rather it reflects the specific expertise that has developed within health psychology and behavioral medicine over recent years. Many of the important medical conditions that concern health psychologists are detailed in later chapters of this volume. The present chapter therefore concentrates on general models rather than specific conditions, and problems such as high blood pressure (hypertension), diabetes mellitus, and bronchial asthma are introduced only for illustrative purposes. The arguments here build on the models of psychophysiological processes in disease that have been presented in earlier publications (Steptoe, 1980, 1984a, 1991).

The major theme of this chapter is that there is now abundant evidence that psychophysiological processes have a role in a range of medical conditions. However, the nature of this role is varied, and depends on the stage of the development of the disorder, and in the ways psychophysiological processes interact with other factors and pathological mechanisms. Psychophysiological processes are implicated as cofactors in medical conditions, rather than exclusive etiological agents. As such, their importance varies across medical problems and between individuals. The era has passed in which certain diseases might be regarded as "psychosomatic," while others were purely biological. Instead, a more fluid concept needs to be understood, in which emotion, behavior, and other psychosocial factors play their parts to a varying extent right across the disease spectrum. Exciting possibilities for management and prevention in the new models of psychophysiological processes are emerging from the literature.

8.02.2 THE PSYCHOPHYSIOLOGICAL RESEARCH FRAMEWORK

Physiological adjustments are associated with the entire range of behavioral states from sleep to vigorous physical exercise. Patterns of blood flow, pulmonary function, gastrointestinal activity, and so on are adapted to sustain the motoric, energetic, and metabolic requirements of the organism. For example, acute exercise is accompanied by an increase in pulmonary ventilation, heart rate and blood pressure, preferential blood flow to skeletal muscle, and mobilization of energy supplies stored in the liver and adipose tissue. These responses maintain adequate glucose supplies to working muscle, and ensure prompt removal of waste products. In the context of disease, the physiological responses that are particularly relevant are those elicited by potential harm. Responses of this kind are typically described as psychophysiological stress responses.

8.02.2.1 Stress and Coping

The definition of psychological stress is an issue that has generated a great deal of discussion and dispute, reflected in the colorful title of the chapter by Engel (1985) *Stress is a noun! No, a verb!, No, an adjective!* It has been argued that stress is a term that is so misused and abused that it be jettisoned altogether as a construct of serious scientific value. Nevertheless, the term has proved difficult to discard, if only as a shorthand to help define a valid area of human experience and clinical importance.

Many of the problems surrounding the concept of stress have stemmed from the definition put forward by an early pioneer, Hans Selye. His definition of stress as the "nonspecific response of the body to any demand" gave rise to two major difficulties. First, the conditions eliciting stress responses were defined so widely (as "any demand") as to be virtually meaningless. The second difficulty is that he introduced the idea of an undifferentiated biological stress response, characterized principally by release of the group of steroid hormones known as glucocorticoids from the adrenal glands. He failed to appreciate that the activation of neuroendocrine, autonomic, and immune pathways is delicately patterned, depending on the precise demands on the organism and the behavioral and cognitive coping responses that are mobilized.

Weiner (1992) has eloquently deconstructed the background to Selye's model, and argues that it arose from the type of animal experiment that was carried out in the middle decades of the century. These studies utilized a variety of intense aversive experiences such as anoxia, limb fracture, extreme cold, and exposure to X rays. They involved potentially life-threatening damage, isolated the organism from its social context, and the stimuli were typically painful, unavoidable, and uncontrollable. These intense experiences, which lacked ecological relevance, masked variations in biological response produced by different contingencies and patterns of coping. They also led to the belief that only very profound and overwhelming experiences were likely to generate damaging physiological change. The remnants of this concept persist in today's literature with the emphasis placed on the study of major life events at the expense of milder everyday aversive experiences that may be cumulatively more significant.

It is now recognized that stress is a biopsychosocial construct, and cannot be defined purely in terms of physiological response. The physiological responses are only part of the profile that include changes at the affective, behavioral, and cognitive levels as well. Nor can stress simply be defined as the response to aversive environmental stimulation or disturbing events. The same situation may produce quite different responses in two people, or in one individual on different occasions. Most frameworks of contemporary research and clinical practice therefore recognize that stress responses arise through interactions between demands on the one hand, and psychosocial resources on the other. Cohen, Kessler, and Gordon (1995a), for example, have defined stress as a process in which "environmental demands tax or exceed the adaptive capacity of an organism, resulting in psychological and biological changes that may place persons at risk for disease" (p. 3).

This process, and the physiological responses that may be elicited, is outlined schematically in Figure 1. The psychosocial demands (or stressors) can be defined as potential or actual threats or challenges to the integrity, survival, and reproduction of the organism (Weiner, 1992). They may be anticipated, and may be real or imaginary. In the field of health psychology, the main categories of psychosocial demand are acute life events, chronic stressors, and day-to-day hassles and irritations. The characteristics of these demands that make them particularly potent elicitors of psychophysiological responses are described in Section 8.02.4.2. Adaptive capacity is operationalized in terms of resistance and vulnerability factors, and

aspects of people's psychological makeup and social world that may render them more or less susceptible. Personality, behavioral coping style, and social resources are among the major resistance and vulnerability factors, and their role is examined in Section 8.02.5. Of course, it must be recognized that although, for convenience, demands and adaptive resources are viewed as distinct categories, they are difficult to disentangle in practice. For example, social isolation can be conceptualized both as the absence of a social resource or as a chronic stressor, while close social contact may be supportive or the source of major interpersonal conflict.

Psychophysiological responses are elicited when the organism's adaptive capacity fails to match demands. Typically, this will be under conditions of over-stimulation, but it is conceivable that lack of stimulation may also lead to adverse physiological change. The physiological responses themselves include adjustment in a number of biological systems, but the most important for health risk are neuroendocrine, immunological and autonomically-mediated changes in physiological function.

8.02.2.2 Research Strategies

Before the physiological systems perturbed by stressful transactions are detailed, a note about research strategies is needed. The clinical literature contains many sceptical comments about psychosocial factors in disease, typically based on negative results emerging from particular studies. It is important to recognize that evidence for a psychophysiological influence on disease does not rest with any one study or even with a single research paradigm. Rather, the evidence is assembled from a range of study types, each with their strengths and limitations.

8.02.2.2.1 Animal studies

Experimental studies with animals can document the ways in which pathological changes may emerge following exposure to different types of behavioral environment. Work with animals allows precise control over genetic background, rearing, and physical surroundings; factors that are difficult to regulate in human studies. Animals can be randomized to different conditions of behavioral stimulation for known periods of time, so true experimental designs are feasible. Detailed physiological assessments are practical, as is concurrent measurement of central neurochemistry.

As noted above, early work with animals tended to utilize physical insults; some of these methods, such as restraint stress, continue to be used (Glavin, Pare, Sandbak, Bakke, & Murison, 1994). Subsequently, experiments in which the behavioral contingencies surrounding physical insults are manipulated have helped to tease out the impact of psychological factors from the effects of pain or tissue damage. There have, for example, been numerous studies comparing controllable and uncontrollable electric shocks matched in intensity and duration, and these have demonstrated pronounced effects of behavioral control (Steptoe & Appels, 1989). However, stressors such as electric shock bear no resemblance to threats that animals encounter in their natural environments, so the value of studies on social challenges has been increasingly recognized. Social disruption and antagonism have been found to influence a range of physiological responses of potential pathological significance including blood pressure, coronary atherosclerosis (Kaplan, Manuck, Williams, & Strawn, 1993), cell-mediated and humorally-mediated immunity (Laudenslager & Fleshner, 1994), visceral fat accumulation (Jayo, Shively, Kaplan, & Manuck, 1993), and renal function (Von Holst, 1972).

Animal studies have clearly demonstrated that behavioral stimuli can elicit physiological responses of pathological significance, and have also underlined the importance of coping behaviors and social position. However, caution is required in their interpretation. Situations that promote pathophysiological responses in some species do not necessarily transfer to others, and there are important strain differences within the species as well (Gilad & Gilad, 1995). The dominant regulatory mechanisms for important target responses are not necessarily the same in different species. For example, glucocorticoids may play a more prominent role in regulating immune function under stress in rodents than in humans, in whom sympathetic pathways are salient (see Section 8.02.3.4). Finally, it is important not to be swayed unduly by superficial similarities between the types of challenge that provoke pathological responses in animal models and the demands to which humans are exposed.

8.02.2.2.2 Mental stress testing

Mental stress testing involves monitoring physiological responses in the laboratory or clinic during exposure to acute psychological challenge. A wide range of mental stress tests are employed, including cognitive and problem-solving tasks, emotionally charged interviews, public speaking tasks, upsetting movies and painful stimuli. Mental stress testing has been a dominant paradigm in cardiovascular research, and has also been utilized to investigate immune, musculoskeletal, respiratory and neuroendocrine responses. Both reactivity and recovery effects may be important (e.g., Seeman & Robbins, 1994).

The value of mental stress testing has been the subject of vigorous dispute. Briefly, the advantage of mental stress testing is that responses to standardized and uniform sets of stimuli can be monitored under environmentally controlled conditions, reducing many of the sources of bias and individual difference that are extraneous to the investigation. Experimental designs can be used with randomization to different conditions, and sophisticated measurement of physiological function is possible in clinical settings. The assertion that responses to mental stress tests show poor reproducibility seems not to be true provided that care is taken with procedures, although adaptation to repeated exposure may occur (Kamarck et al., 1992). However, there are other limitations. One is that use of standardized stimuli means that conditions may be somewhat divorced from everyday life. Few people spend much of their lives carrying out mental arithmetic under time pressure, or having ice packs placed on their foreheads. The monitoring of physiological activity during conversation and speech tasks goes some way towards evaluating ecologically more relevant situations. Second, physiological responses to standardized conditions may not always be representative of function outside the laboratory or clinic.

8.02.2.2.3 Field studies

Field studies are naturalistic investigations in which physiological measures are obtained while people go about their lives outside the laboratory or clinic. By taking repeated measures, it is possible to monitor the pattern of response to real-life stressors, or to assess associations with fluctuations in behavioral and emotional state. Three types of field study are relevant to psychophysiological aspects of disease. The first involves recording during challenging tasks such as parachuting, learning to fly aeroplanes, or speaking in public (e.g., Biselli, Farrace, Amelio, & Fattorossi, 1993; Van Doornen & Van Blokland, 1992). These investigations are closest to laboratory studies in that they evaluate responses to acute and relatively unusual events. The second type of study involves repeated assessments of physiological parameters as people go about their ordinary lives. For example, repeated samples of saliva can been obtained over the day and analyzed to measure the profile of cortisol release in people exposed to different levels of daily stress (Van Eck, Berkhof, Nicolson, & Sulon, 1996). The third type of field study involves using automated portable (ambulatory) apparatus to measure physiological activity in a relatively unobtrusive fashion from free living individuals. For instance, portable electrocardiograms (EKG) and ambulatory blood pressure monitoring equipment have proved valuable for assessing psychosocial factors related to cardiovascular disease, while electromyographic (EMG) assessments of muscle tension in the neck and forehead are feasible for the investigation of headache (Hatch et al., 1991 Pickering, 1991).

The main advantage of field studies is that they have ecological validity, in that physiological measures are obtained under naturalistic conditions of ongoing behavior and emotion. Studies of blood pressure in patients with hypertension suggest that ambulatory measures are even more predictive of pathological progression than are measures taken in the clinic (Pickering, 1991). The limits of field measures are essentially technological, but developments of instrumentation mean that even rather complex functions such as the dynamics of the filling and contraction of the heart can now be monitored.

There are, however, a number of factors that need to be borne in mind when interpreting these data. The first is that field measures are inevitably somewhat disturbing, since people are aware of the apparatus and may modify their behavioral responses. One study of ambulatory blood pressure demonstrated that in comparison with a control day, people were less physically active on the measurement day, and rested more (Blanchard, Cornish, Wittrock, & Jaccard, 1990). Second, there are numerous extrinsic influences on physiological function that need to be taken into account, including cigarette smoking, food and caffeine intake, and patterns of sleep and activity. Perhaps most problematic is distinguishing physiological responses related to physical activity and exertion from those elicited by psychosocial factors. For example, we have recently studied ambulatory blood pressure monitored from a group of men during an eight-hour work shift, and a comparable nonwork period (Steptoe, Roy, & Evans, 1996). Blood pressure was recorded every hour using portable apparatus, and ratings of activities were made in diaries. As might be expected, blood pressure was higher over the work than nonwork day, and the men also reported more frequent stress at work. However, the blood pressure readings were more likely to be associated with high physical activity at work than during nonwork periods, and this may have accounted in part for differences between the days. Sophisticated analytic procedures are required to take account of these factors (Schwartz, Warren, & Pickering, 1994).

8.02.2.2.4 Survey studies

The last type of study in which psychophysiological processes are evaluated involves measurement of physiological parameters in epidemiological surveys or in clinical samples. Typically, the physiological markers are recorded on a single occasion rather than repeatedly, with efforts being made to standardize recording conditions as far as possible. It is sampling of this type that established high blood pressure and elevated serum cholesterol concentration as standard risk factors for coronary heart disease, and recent years have witnessed extension of the methodology to the study of psychosocial factors. For instance, the relationship between blood pressure and psychological characteristics such as anger has been assessed in several surveys (Jorgensen, Johnson, Schreer, & Kolodziej, 1996). Immune measures derived from single blood samples have been shown to be disturbed in people under the chronic burden of caring for dementing relatives (Kiecolt-Glaser, Dura, Speicher, Trask, & Glaser, 1991). Concentration of fibrinogen, a substance involved in the process of blood clotting, has been related to social class, and may contribute to the socioeconomic gradient in coronary heart disease (Markowe et al., 1985).

Survey studies are valuable in identifying the biological parameters relevant to the influence of psychosocial disturbances on disease risk. Measures from large representative samples can be obtained at relatively low cost, prospective study designs can be employed, and potential confounders can be taken into account by statistical manipulation. However, survey studies provide limited information about the dynamics of physiological responses, their origins or consequences, and the causal sequences are often difficult to disentangle.

8.02.2.2.5 Convergence of methods

Efforts are increasingly being made to integrate the different methods outlined here. This trend has been particularly prominent in the cardiovascular area, with work on the interrelationship between responses to mental stress testing and ambulatory cardiovascular monitoring. The aim has been to discover whether acute blood pressure responses during behavioral tasks correlate with blood pressure levels recorded under naturalistic conditions (Turner et al., 1994). Another example is the extension of mental stress testing into the epidemiological framework, replacing the small selected samples typical of laboratory studies by large-scale evaluations (Carroll, Smith, Sheffield, Shipley, & Marmot, 1995). Developments in instrumentation technology are likely to promote this important trend, since at present the results of investigations carried out with different study types are often difficult to compare directly.

8.02.3 PSYCHOPHYSIOLOGICAL RESPONSES

The psychophysiological responses relevant to disease are many and varied. Each system has a complex organization involving the integration of autonomic, hormonal, and metabolic regulatory processes. The brain mechanisms responsible are also complicated, and several neurotransmitters are implicated, including serotonin, gamma-aminobutyric acid and dopamine (Gray, 1995; Williams, 1994). The aim here is to describe the major psychophysiological responses currently thought to be relevant to disease, and briefly to outline their regulation and effects. More detailed accounts will be cited where appropriate. Measurement issues will not be discussed, since there are texts directly devoted to these topics (Cohen, Kessler, & Gordon, 1995b).

8.02.3.1 Neuroendocrine Parameters

8.02.3.1.1 Adrenal steroid stress response

The adrenal steroids known as corticosteroids have held center stage in research on psychophysiological aspects of disease for many decades, largely as a result of Selye's work. There is, however, a growing feeling among investigators that this emphasis may be misplaced, originating as it does in rodent biology. In humans, the sympathetic nervous system and the catecholamines may be more important as mediators of peripheral physiological dysfunction. Nonetheless, there is no doubt about the extensive effects of corticosteroid release. Corticosteroids are produced by the cortex of the adrenal glands as a result of activity in the hypothalamic–pituitary–adrenal (HPA) axis. Neurosecretory neurons in the paraventricular nuclei of the hypothalamus contain a peptide called corticotropin releasing factor (CRF), which is transported through the hypothalamic hypophyseal portal system to the pituitary where it initiates the synthesis of adrenocorticotropin (ACTH) and beta-endorphin. The amygdala is in part responsible for stimulating CRF in response to stressors, while the hippocampus plays an inhibitory role (McEwen & Sapolsky, 1995). ACTH in turn travels through the circulatory system to the adrenal glands, where it stimulates production of steroid hormones such as androgens, estrogens, mineralocorticoids and glucocorticoids. The most important corticosteroid in the stress response is the glucocorticoid cortisol (corticosterone in rodents).

Corticosteroid production is regulated through negative feedback loops to the hippocampus, hypothalamus, and pituitary gland. Corticosteroid receptors in the hippocampus mediate a fast feedback loop responding to increases in plasma corticosteroids by inhibiting the HPA, while glucocorticoids inhibit CRF biosynthesis in the hypothalamus and ACTH release in the pituitary through a delayed feedback circuit that responds to tonic corticosteroid levels (Checkley, 1996). The dexamethasone suppression test is a method of assessing the feedback loop by measuring the suppression of HPA function with a synthetic glucocorticoid. Other important regulators of the HPA axis are cytokines, peptides released by activated immune cells that act on the brain structures involved in corticosteroid release, and these processes will be described in Section 8.02.3.4 (Besedovsky & Del Rey, 1996). Together, the regulatory mechanisms ensure that under normal circumstances, corticosteroid production is maintained within a narrow range.

Much of the cortisol secreted by the adrenals is inactive and bound to carriers. Free corticosteroids have a range of actions including stimulation of glucose production by the liver, the release of free fatty acids from adipose fat stores, the modification of water balance, alteration in vascular tone and the excretion of sodium by the kidney, the promotion of anti-inflammatory responses, and immunoregulatory effects. Disruption of corticosteroid output during stress responses may have a variety of adverse effects such as the elevation of lipid concentration in the bloodstream (which may in turn be incorporated into atherosclerotic plaque), deposition of fat in abdominal adipose tissue, the suppression of some immune functions, decalcification of bone, and impaired fertility (Sapolsky, 1992; Weiner, 1992). There is evidence that blood pressure increases with glucocorticoid stimulation, and cardiovascular reactivity to sympathetic nervous stimulation is enhanced (Whitworth, Gordon, Andrews, &

Scoggins, 1989). Within the central nervous system, sustained elevation of glucocorticoid concentration may lead to damage of the hippocampus, attenuating the hippocampal inhibition of CRF production. Increased levels of glucocorticoids are associated with clinical depression, and may promote hippocampal atrophy in humans (Holsboer & Barden, 1996).

Increased cortisol has been observed under a range of acutely challenging conditions in humans and animals. Early work in this area was reviewed by Mason (1968) who did much to dispel the notion that corticosteroid production bears a simple linear association with the emotional distress. Increased cortisol in the blood, urine, and saliva is found in response to mental arithmetic, speech tasks, simulated driving, and other challenges (e.g., Kirschbaum et al., 1995; Seeman et al., 1995). Chronic stress in animals has been shown to lead to a reduction in the number of corticosteroid receptors in the hippocampus, impairment of central nervous system inhibition of the HPA, and hypertrophy of the adrenal glands (Herman, Adams, & Prewitt, 1995). Results of studies of naturalistic stressors in humans have been somewhat variable, partly because measurement is complicated by circadian variations and the influence of factors such as physical exercise, smoking, caffeine, alcohol, and medication. A longitudinal investigation of an elderly population showed that plasma cortisol was elevated up to three months following severely threatening life events, and cortisol elevations are particularly marked among depressed people who experience long-term stressors (Willis, Thomas, Garry, & Goodwin, 1987). High cortisol has also been recorded from people exposed to major threats such as being a hostage of war (Rahe, Karson, Howard, Rubin, & Poland, 1990). On the other hand, ex-soldiers suffering from post-traumatic stress disorder show low cortisol levels, and an inverse relationship with intensity of combat exposure has been described (Boscarino, 1996).

Despite the opinion that many types of work are stressful, the results of investigations of corticosteroid levels in people at work have been inconsistent, and it appears that only a proportion of individuals respond even to very challenging occupations such as air traffic control (Rose & Fogg, 1993). Nonetheless, day-to-day stressors or hassles have been found to stimulate increased cortisol independently of factors such as smoking, food intake, and coffee consumption (Van Eck et al., 1996). There is sufficient evidence to infer that heightened cortisol secretion may be a mechanism through which psychophysiological factors influence risk of disease.

8.02.3.1.2 Catecholamines and the sympathetic nervous system

The autonomic nervous system is the branch of the nervous system that regulates the function of visceral organs, and has two divisions, the sympathetic and the parasympathetic. Many tissues are dually innervated, with stimulation of the sympathetic and parasympathetic nerves having opposite effects. For instance, heart rate accelerates under sympathetic stimulation and slows with parasympathetic (vagal) stimulation. The major neurotransmitter in the sympathetic nervous system is norepinephrine (noradrenaline) while acetylcholine is released from parasympathetic nerve terminals.

The sympathetic nervous system tends to induce activation in many tissues, so the second major component of the psychophysiological stress response is the sympathetic-adrenomedullary (or sympathoadrenal) system. Norepinephrine is stored in granules in the sympathetic nerve terminals, and is released when these nerves are stimulated. Much of the neurotransmitter binds to alpha-adrenergic and beta-adrenergic receptors on effector cells, while the remainder is released into the bloodstream. Sympathetic pathways also stimulate the synthesis of epinephrine (adrenaline) in the chromaffin cells of the adrenal medulla. A series of enzymes are involved in this process, including tyrosine hydroxylase, dopamine beta-hydroxylase, and phenylethanolamine *N*-methyltransferase, that are sometimes measured as indices of catecholamine production. The sympathetic nervous system and epinephrine from the adrenal glands typically operate in concert to stimulate a wide range of physiological responses that are summarized in Sections 8.02.3.2–8.02.3.4.

Catecholamine levels in the bloodstream are not easy to measure since responses are rapid and transient, and concentrations in venous blood may not be representative of the overall level of circulating epinephrine and norepinephrine. Other techniques such as the measurement of norepinephrine spill-over from nerve terminals, electrical recording from sympathetic nerves using microneurography, and measures of adrenergic receptor density provide more direct information. These techniques indicate that sympathetic activation is not a generalized phenomenon with mental stress, since the degree of sympathetic response differs substantially across tissues (e.g., Anderson, Wallin, & Mark, 1987). However, most human laboratory and field studies have measured catecholamines from venous blood samples or from urine. In the laboratory, acute increases in epinephrine and norepinephrine have been recorded in response to mental stress tests such as arithmetic, cold stimulation, and social conflict (Malarkey, Kiecolt-Glaser, Pearl, & Glaser, 1994). In field studies, elevations of catecholamines have been shown in diverse groups including the bereaved and victims of industrial disasters and sexual abuse (De Bellis, Lefter, Trickett, & Putnam, 1994; Gatchel, Schaeffer, & Baum, 1985).

A substantial amount of research has been carried out into sympathoadrenal responses to work. Studies from Sweden have shown that catecholamine excretion is elevated among people on piece work or those carrying out highly mechanized work (Johansson, Aronsson, & Lindstrom, 1978). Differences between sexes and people at higher and lower work grades have been reported, with some evidence for sustained elevations of norepinephrine in the evening among women in managerial positions (Frankenhaeuser et al., 1989). Frankenhaeuser, Lundberg, and Forsman (1980) have argued that behavioral performance efficiency under challenging conditions is positively associated with catecholamine secretion. However, one of the problems interpreting catecholamine responses is that excretion is positively correlated with physical effort and with motor activity; consequently, norepinephrine may increase when people are more actively engaged in tasks.

The sympathoadrenal system and the HPA axis are not independent of one another. The glucocorticoids have a role in regulating catecholamine biosynthesis in the adrenal medulla, while catecholamines stimulate ACTH release from the pituitary (Axelrod & Reisine, 1984). Under acute conditions, correlations have been observed between cortisol and sympathetically mediated responses in some but not all studies (Cacioppo, 1994). At the same time, there has been great interest in identifying situations that lead to differential release of corticosteroids and catecholamines. Extensive evidence (reviewed by Steptoe, 1983) suggests that HPA activation is associated with passivity in the face of aversive situations, with behavioral withdrawal, and with loss of control. Sympathoadrenal responses on the other hand are maximized under conditions of active efforts to cope and maintain control over the environment. This distinction may be significant when examining psychophysiological pathways to disease.

8.02.3.1.3 Endogenous opioids

Beta-endorphin and the enkephalins are endogenous opioid peptides, and are derived from the same precursor molecule as ACTH. The secretion of beta-endorphin from the anterior lobe of the pituitary gland is regulated by CRF, and occurs in response to a wide range of painful stimuli and stressors (Madden, Akil, Patrick, & Barchas, 1977). Inescapable electric shock in rats has been shown to produce stress-induced analgesia or increased pain tolerance. One form of this analgesia is dependent on endogenous opioids, in that it is blocked by antagonists such as naloxone, and shows cross-tolerance with morphine-induced analgesia (Terman, Shavit, Lewis, Cannon, & Liebeskind, 1984).

There is growing evidence that endogenous opioids are involved in the regulation of neuroendocrine stress responses (McCubbin, 1993). Serum concentration of beta-endorphin increases during mental stress tests, and assessments have also been made during naturalistic challenges such as anticipation of academic examinations (Malarkey, Pearl, Demers, Kiecolt-Glaser, & Glaser 1995; Sheps et al., 1995). When the opioid antagonist naloxone is administered under double-blind conditions, it leads to increases in stress-induced heart rate, epinephrine, ACTH and cortisol responses (Morris et al., 1990). This suggests that beta-endorphin normally operates to dampen excessive responses, and is part of the organism's self-regulatory mechanism, preventing overshoot of stress-induced physiological reactions. The pathway may operate less effectively in young people at elevated risk for high blood pressure, since their cardiovascular responses to mental stressors are unchanged by naloxone (McCubbin, Surwit, Williams, Nemeroff, & McNeilly, 1989). The increase in beta-endorphin with mental stress has been shown to correlate with raised pain thresholds in patients with coronary artery disease (Sheps et al., 1995). This may be one explanation for stress-induced episodes of reduced coronary blood flow (ischemia) occurring without concomitant chest pain in so-called "silent" ischemia.

8.02.3.1.4 Other neuroendocrine and hormonal responses

A range of other hormones are involved in psychophysiological responses. Dopamine in the brain increases in response to experimental stressors in animals, and peripheral dopamine may be particularly important in modulating gastrointestinal injury (Glavin, 1992). Reproductive function is inhibited by various components of the HPA system, with suppression of luteinizing hormone releasing hormone in the hypothalamus, and inhibition of testosterone and estrogen by glucocorticoids (Rabin, Gold, Margioris, & Chrousos, 1988). The classic studies of Christian (1970) showed that crowding in animals impaired reproductive efficiency. Social status has also been shown to affect ovarian function in cynomolgus monkeys, with more anovulatory cycles and progesterone-deficient luteal phases in subordinate animals (Adams, Kaplan, Clarkson, & Koritnik, 1985). Hypogonadal function in middle-aged men is associated with psychosocial risks such as work-related problems, living alone, lower social class, and high levels of physical symptoms (Nilsson, Moller, & Solstad, 1995). Vasopressin and prolactin have also been studied as components of psychophysiological responses, although their significance is not yet clear (Theorell, 1992).

8.02.3.2 Cardiovascular and Autonomic Parameters

Psychophysiological responses are organized hierarchically, and a series of physiological adjustments take place as a result of the neuroendocrine secretions described in Section 8.02.3.1 coupled with direct autonomic stimulation. They include changes in cardiovascular function, sweat gland activity, gastrointestinal motility and pulmonary ventilation. Not all of these responses are immediately relevant to disease risk. Studies using direct stimulation of brain regions in unanaesthetized animals indicate that emotional behaviors can be elicited that are associated with a range of damaging physiological changes such as cardiac arrhythmias, gastric erosions, and adrenal hyperplasia (Kojima et al., 1996). Cardiovascular and metabolic responses are particularly important when considering psychophysiological processes in disease.

8.02.3.2.1 Blood pressure, heart rate, and regional blood flow

Blood pressure and heart rate generally increase in response to acute challenges in the laboratory. During performance of tasks such as mental arithmetic, the increase in blood pressure and heart rate is associated with vasodilation in skeletal muscle and reduced blood flow to the kidneys, skin, and viscera (Tidgren & Hjemdahl, 1989). The high heart rate (tachycardia) is a result of sympathetic stimulation coupled with parasympathetic or vagal withdrawal. Blood flow in adipose tissue is increased, and is associated with enhanced lipolysis (Linde, Hjemdahl, Freyschuss, & Juhlin-Dannfelt, 1989). The sensitivity of the cardiac baroreceptor reflex, the mechanism through which increased blood pressure is offset by slower heart rates and vice versa, is inhibited during acute stress. Power spectrum analysis of heart rate and blood pressure signals show changes in spectral density at different frequencies indicative of these autonomic adjustments (Pagani et al., 1991). The capacity of the kidneys to excrete sodium and maintain fluid balance may also be impaired, and this may have implications for the development of hypertension (Light, Koepke, Obrist, & Willis, 1983).

Several factors need to be taken into account when evaluating acute stress responses in humans. First, response patterns depend critically on the nature of the demands imposed on the individual. Actively demanding situations such as information processing and problem solving tend to elicit cardiovascular responses that are mediated by increases in myocardial contractility leading to elevated stroke volume and cardiac output. In contrast, passive aversive conditions and situations over which people have little control elicit increases in peripheral resistance rather than cardiac responses (Sherwood, Dolan, & Light, 1990). Consequently, it is not appropriate to regard the cardiovascular response to acute stressors as a uniform phenomenon.

Second, individuals show characteristic response patterns that persist across different situations. Manuck (1994) identified groups of "cardiac" and "vascular" reactors, according to whether they showed increases in cardiac activity or total peripheral resistance during tasks. The magnitude of blood pressure response was similar in the two groups despite variation in the underlying pattern of haemodynamic adjustment. This means that individual differences as well as situational characteristics need to be taken into account (see also Section 8.02.6.7).

Third, there appears to be flexibility across hemodynamic mechanisms, so that certain aspects of cardiovascular responses are maintained during mental stress through alternative pathways when necessary. For example, when actively demanding mental stress tests are carried out during inhibition of sympathetic pathways by beta-adrenergic blockade, blood pressure elevations are maintained through other autonomic mechanisms (Julius, (1988). Similarly, adrenelectomized subjects show the same blood pressure response to mental arithmetic or other stimuli as healthy controls, despite the lack of epinephrine response and a reduced heart rate increase (Lenders, Peters, Pieters, Willemsen, & Thien, 1988). Julius (1988) had described this as a "blood pressure-seeking property" of the central nervous system, with integrative mechanisms in the brain operating to maintain sustained high blood pressure during challenge through a variety of physiological mechanisms. If this is true, it has important implications for interventions designed to reduce blood pressure stress responses.

8.02.3.2.2 Cardiac function

Several aspects of cardiac function may be disturbed as part of the psychophysiological stress response in vulnerable individuals (see Steptoe & Tavazzi, 1996). The two most important types of response are changes in the rhythm of cardiac contraction and alterations in blood flow in the coronary circulation.

Clinical disturbances of the generation and conduction of heart beats include various types of tachycardia and arrhythmia (Janse & Davies, 1996). Arrhythmias affecting the left ventricle of the heart (ventricular arrhythmias) can be provoked by sympathetic nervous stimulation, while the parasympathetic system is protective. Stimulation of the posterior hypothalamus in dogs reduces the threshold for potentially lethal ventricular fibrillation, and similar responses have been observed during avoidance conditioning and other types of psychological stress (Lown, Verrier, & Rabinowitz, 1977). In cardiac patients, ventricular arrhythmias have been associated with high levels of norepinephrine spill-over indicative of sympathetic activity (Meredith, Broughton, Jennings, & Esler, 1991). Tavazzi, Zotti, and Rondanelli (1986) evaluated the influence of mental stress on the electrophysiology of the heart using programed ventricular stimulation in postinfarction patients. Transient ventricular tachycardia and fibrillation were induced in patients during psychological stress, but not under resting control conditions. These studies suggest that the disturbances of cardiac rhythm can be induced by activation of psychophysiological pathways.

High levels of parasympathetic or vagal tone act in opposition to sympathetic traffic, and reduce vulnerability to certain arrhythmias. Clinically, it has been observed that high heart rate, which may be a reflection of low vagal activity, may be an independent risk factor for coronary heart disease (Dyer et al., 1980). The minimum heart rate achieved during 24-hour ambulatory monitoring is positively associated with coronary atherosclerosis as determined by angiography (Perski et al., 1992). Parasympathetic activity is also related to heart rate variability, with higher variability being indicative of greater parasympathetic tone. Mortality in postmyocardial infarction patients has been related to low heart rate variability, and this may be another important marker of the psychophysiological response (Klieger, Miller, Bigger, & Moss, 1987).

Blood flow abnormalities in the coronary circulation can provoke ischemia and abnormalities of contractility and left ventricular wall motion. In classical angina pectoris, cardiac ischemia due to increased myocardial oxygen demand during exercise is associated with chest pain, but episodes of "silent" ischemia (without pain) are also common. Mental stress may stimulate cardiac ischemia in a manner similar to exercise, with raised blood pressure and heart rate leading to heightened myocardial oxygen demand. Alternatively, there may be a direct influence of the central nervous system on the vascular tone of the coronary arteries and arterioles, leading to reductions in coronary blood flow.

Sustained infusions of norepinephrine have been shown to induce myocardial lesions indicative of ischemia (Schenk & Moss, 1966). Several new methods of assessing cardiac function in conscious people have allowed stress-induced silent ischemia to be evaluated in detail. In an early study, positron tomography was used in a study of 16 angina patients (Deanfield et al., 1984). Twelve patients showed abnormalities of perfusion of the heart during mental arithmetic, but pain was experienced by only four. Rozanski et al. (1988) documented a high incidence of left ventricular wall motion abnormalities during mental stress in patients with coronary artery disease using radionuclide ventriculography, with public speaking being a particularly provocative stress test. Similar results have emerged with other methods (Steptoe & Tavazzi, 1996).

Studies of ischemic responses under field conditions have largely been confined to examining abnormalities of the EKG rather than more sensitive measures, although the introduction of the ambulatory "nuclear vest" may be helpful in the future (Legault, Freeman, Langer, & Armstrong, 1995). Gabbay et al. (1996) assessed the frequency of ST-segment depression (an EKG change indicative of myocardial ischemia) in patients during ambulatory monitoring. It was found that both physical exertion and mental stress (anxiety and anger) were associated with ischemic episodes. The presence of ischemic responses to mental stress in the laboratory has recently been found to predict silent ischemia during ambulatory monitoring in a large sample of patients with coronary artery disease (Blumenthal et al., 1995). Interestingly, positive correlations have also been recorded between the number and duration of ischemic episodes in daily life, and heart rate responses to mental stress in the laboratory (Krittayaphong, Light, Biles, Ballenger, & Sheps, 1995). These results indicate that laboratory responses to mental stress may have genuine significance for cardiac function in patients with coronary artery disease.

8.02.3.2.3 Platelets and hemostasis

The ability of blood to coagulate rapidly is one of the primary defense mechanisms reducing the impact of injury. One of the early stages of the clotting process is the adhesion of blood platelets to the lips of a wound and the formation of a platelet plug. This is followed by reinforcement of the platelet plug with fibrin. Later the deposit is removed by fibrinolytic and other mechanisms. This process is also involved in the formation of the thrombi in the vascular system that contribute to clinical events such as myocardial infarction and stroke.

It has been known for many decades that catecholamines stimulate the activation of platelets and their aggregation (Ardlie, Glew, & Schwartz, 1966). Platelet activation and aggregation have been shown to increase in healthy subjects carrying out challenging mental stress tests (Larsson, Hjemdahl, Olsson, Egberg, & Hornstra, 1989). Rapid increases in platelet activation and aggregability have also been recorded in patients with coronary artery disease performing mental arithmetic (Grignani et al., 1991). The implication of such findings is that vulnerability to the formation of thrombi may be enhanced as part of the psychophysiological stress response. Unfortunately, results of naturalistic studies have been rather inconsistent, with both increases and decreases in platelet activation and aggregation being reported under challenging conditions (Haft & Arkel, 1976, Levine et al., 1985). One complication is that there are several markers of platelet function and they may not produce uniform results.

The later stages of the coagulation cascade culminate in the action of the enzyme thrombin, which converts fibrinogen into fibrin. There has been limited study of this process in the psychophysiological context, although one study showed a decrease in fibrinogen and other blood coagulation factors during a prolonged episode of work without sleep (Palmblad et al., 1977), while work stress has been associated with elevated fibrinogen levels (Davis, Matthews, Meilahn, & Kiss, 1995).

8.02.3.2.4 Other physiological systems

Respiration is regulated by brain stem mechanisms that are closely integrated with cardiovascular control systems. During challenges that involve active efforts to cope, increases in respiration rate are typically observed, while the depth of breathing (tidal volume) is augmented. Changes in the constriction of the airways can also be induced as part of the psychophysiological stress response. Restriction of the airways (or bronchoconstriction) is stimulated not by the sympathetic but by the parasympathetic nervous system, while epinephrine relaxes the smooth muscle of the bronchial tree. The airways therefore operate in the opposite fashion to cardiovascular parameters, in that problems are more likely to be induced by parasympathetic than sympathetic stimulation. Effects are found most prominently among people suffering from bronchial asthma, for whom challenges such as the suggestion that an agent which causes wheezing is being inhaled can stimulate pronounced bronchoconstriction (Steptoe, 1984b). These responses are blocked by atropine and other anticholinergic agents, confirming that the parasympathetic nervous system is involved. Passive aversive situations in which the person is not required to respond actively but rather to endure stressful conditions are especially provocative (Lehrer et al., 1996). There is some evidence that bronchoconstrictive responses can be elicited in nonasthmatics as well as asthmatic individuals, but the findings are controversial.

The gastrointestinal tract is innervated by the autonomic nervous system in such a way that stimulation of the sympathetic branch decreases digestive functions such as saliva production, bile secretion, and gut motility, while these processes are enhanced by ACTH and parasympathetic responses. Large individual differences have been recorded in studies of gastric acid secretion with mental stress (Holtmann, Kriebel, & Singer, 1990). Thompson, Richelson, and Malagelada (1982) have shown how a variety of acute stressors, such as the cold pressor test or ear irrigation with cold water, delay gastric emptying and perturb duodenal motility. Other measures of gastrointestinal function are disturbed with acute stressors in people suffering from disorders such as duodenal ulcer and irritable bowel syndrome (Kumar & Wingate, 1985).

Changes in skeletal muscle tension are important components of the psychobiological stress response. These reactions are difficult to quantify without elaborate instrumentation, since no one set of muscles is a reliable indicator of general tension. Levels of tension in various tissues are heightened among patients with anxiety disorders, and acute stressors may also affect both level and variability of muscle tension (Hoehn-Saric, McLeod, & Zimmerli, 1989). The role of these responses in headache and low back pain is discussed in further detail in Section 8.02.7.3.

8.02.3.3 Lipids and Glucose Metabolism

The level of blood cholesterol is well recognized as a risk factor for coronary artery disease, so the influence of psychosocial factors on cholesterol metabolism is of great interest. Cholesterol is a fat-like material synthesized mainly in the liver, and is transported through the circulation in the form of lipoprotein particles. These protein molecules are of several types. Low-density lipoproteins (LDL) carry much of the cholesterol, and are the main culprit in coronary artery disease. High-density lipoproteins (HDL) also carry cholesterol but are protective in that they clear lipid from blood vessel walls. In addition, triglycerides are fats that are not attached to proteins; they may be associated independently with cardiovascular disease risk, although the importance of this mechanism remains uncertain.

Indirect evidence for the involvement of psychophysiological stress responses in lipid metabolism comes from experiments showing that blood pressure, heart rate, and catecholamine responses are correlated with the concentration of cholesterol and lipid fractions (e.g., Fredrikson, Lundberg, & Tuomisto, 1991; Suarez, Williams, Kuhn, Zimmerman, & Schanberg, 1991). If people prone to large physiological stress responses show higher lipid levels, then a common pathway of sympathetic or HPA activation may be responsible. Psychological challenges can also lead to acute increases in total cholesterol and LDL-cholesterol concentration (McCann et al., 1995). However, it has been discovered that this response may be secondary to alterations in blood volume. Plasma volume shows small reductions during mental stress tests because of shifts between intra-cellular and extra-cellular compartments. This can lead to an increase in blood protein concentration that accounts for the apparent elevation in blood lipid levels.

The impact on lipids of longer-term stressors such as anticipation of academic examinations, stressful work, and threat of unemployment has also been evaluated (Brindley, McCann, Niaura, Stoney, & Suarez, 1993). Results have been quite mixed, with increases in total cholesterol and LDL-cholesterol in some studies but not others. The problem in understanding these responses is that under naturalistic conditions, changes may take place in dietary composition, smoking, and other factors that influence lipids independently of any psychophysiological processes. Clearer evidence derives from animal studies in which diet and other factors can be controlled. Infusion of epinephrine has been shown to increase cholesterol concentration in primates and rodents, while socially subordinate baboons have lower HDL-cholesterol than dominant animals, and this is coupled with a higher cortisol concentration (Sapolsky & Mott, 1987). However, it is striking that in the series of studies of social stress in cynomolgus monkeys carried out by Kaplan, Manuck and co-workers, increases in coronary atherosclerosis have been observed that were not due to elevations in lipid concentration (Kaplan et al., 1993; Manuck, Kaplan, Adams, & Clarkson, 1989). In this animal model, social stress promotes atherosclerosis independently of lipid concentration, through mechanisms such as damage to the endothelial surface of arterial walls, which may permit greater deposition of lipids in vessel walls (Strawn et al., 1991).

8.02.3.3.1 Insulin metabolism and abdominal obesity

One of the critical mechanisms linking neuroendocrine activation with lipid metabolism is insulin. Insulin is a hormone produced by the cells of the Islets of Langerhans in the pancreas, and facilitates the utilization of glucose by tissues. Destruction of the insulin-producing cells leads to insulin-dependent (or Type 1) diabetes mellitus, in which protein and fat are metabolized instead of glucose, resulting in accumulation of toxic substances in the blood and kidney damage. A more common disorder is noninsulin dependent (or Type II) diabetes, in which high levels of circulating glucose (hyperglycemia) arise either because of failure to produce adequate insulin, or because of defects in the ability of tissues to respond to insulin (insulin-resistance).

Both the sympathoadrenal and HPA axes influence insulin metabolism, affecting its secretion, the conversion of glycogen to glucose in the liver, and glucose uptake in tissues. A constellation of metabolic disturbances (sometimes known as syndrome X or the insulin resistance syndrome) coexist in people at raised risk for cardiovascular disease. Their problems include insulin resistance, hyperinsulinemia, glucose intolerance, low concentrations of HDL-cholesterol and high blood pressure (Reaven, 1988). Another element of this risk profile is obesity, due particularly to deposition of fat in the central or abdominal fat stores. Bjorntorp (1990) has argued that a disturbance of corticosteroid control over lipid metabolism may underlie the development of abdominal obesity. Cortisol responses to mental stress tests have been shown to correlate positively with the degree of abdominal obesity (Moyer et al., 1994), while animal studies have demonstrated that social stress promotes deposition of abdominal fat (Jayo et al., 1993). It appears, therefore, that lipid and glucose metabolism play important roles in psychophysiological responses, and may be relevant to the pathogenesis of coronary heart disease and diabetes.

8.02.3.4 Immune Parameters

One of the most exciting developments in the psychophysiological studies of disease over recent decades has been the discovery that immune function may alter as part of the stress response. Knowledge of these links increases understanding of the mechanisms through which psychosocial factors can influence vulnerability to infection, inflammation, autoimmune disease, and certain types of cancer. Sweeping assertions that stress suppresses immune function are not appropriate, since it is now recognized that the central nervous system and immune system engage in a complex interplay, and that immune responses can be both up-regulated and down-regulated by different behavioral and emotional states.

The immune system is the body's primary defense against infection and invading pathogens such as viruses, bacteria, and fungi. Some immunity is innate and is present from birth, acting nonspecifically to protect against foreign materials. The skin and mucus membranes are part of this innate immune defence, using autonomic and chemical methods to prevent invasion, while cells such as macrophages are also involved. Local invasion can also trigger a general or systemic "acute phase response," in which several general bodily processes are elicited, including fever and raised body temperature.

Although the innate system is highly effective, it cannot cope with all pathogens, so there is a second form of immunity which is acquired or specific. Acquired immunity involves the recognition of substances (antigens) as "nonself," and the destruction or elimination of these materials. The immune system has memory, reflected in the fact that secondary exposure to antigens elicits a more vigorous immune response than the initial reaction, although the mechanism is poorly understood (Ahmed & Gray, 1996). The main organs of the immune system include the bone marrow, thymus gland, spleen, and lymphatics, but there are also cells active in the skin, lungs and gut.

There are two major arms of the immune system. Humoral immunity is involved in defense against bacteria and viruses in body fluids, while cell-mediated immunity is relevant to intracellular viruses and fungi, and also to cancer cells and transplanted tissue. Humoral immunity is mediated by serum antibodies or immunoglobulins. These are proteins that derive from B-lymphocytes in the bone marrow, and react with specific antigens. There are five major classes of immunoglobulin, IgA, IgM, IgG, IgE, and IgD, and each has unique characteristics. For example, IgE has a primary role in defense against parasites, and elicits a range of responses designed to exclude these organisms including bronchoconstriction, vomiting, inflammation, itching, and coughing. It also has a key role in allergic responses which are generally caused by overproduction of IgE (Sutton & Gould, 1993). IgA is found in secretions such as saliva and tears, and is important in defense against local infections in the gut and respiratory system.

Cellular immunity involves T-lymphocytes that arise in the bone marrow and mature in the thymus before circulating in the blood and lymph. T-cells do not recognize antigens by themselves, so antigens are usually presented to them by macrophages. T-cells have to be activated, but once activated become memory cells, migrating to tissues in which they are most likely to re-encounter their specific activating antigen. They are differentiated into various types. Of particular importance to work on stress and immune function are cytotoxic T-lymphocytes that kill invading pathogens and are involved in defense against infections such as influenza and the herpes simplex virus. T-cells are classified by surface cell markers, and cytotoxic T-cells fall into the CD8+ class. Helper T-cells (CD4+) play a central regulatory role in immune defense, stimulating B-cells to produce antibody, activating macrophages to engage in antimicrobial activity, and cytotoxic T-cells. Some of these actions are mediated through immune products called cytokines that have very specific actions on other branches of the immune system. Another type of lymphocyte, the suppressor T-cell, largely falls into the CD8+ category, but is less well understood. Suppressor cells are thought to shut off the activity of helper cells, and the helper/cytotoxic-suppressor ratio is sometimes assessed as a marker of immune health. Natural killer cells are a further class of immune cell, and are involved in immune surveillance, acting nonspecifically to defend against certain tumor cells and virus-infected cells.

Many different assays of immune function have been used in the context of health psychology (Kiecolt-Glaser & Glaser, 1995). They include enumerative assays or counts of various cell types, measures of concentration of immunoglobulins in the blood and saliva, measures of cytokine activity, and functional assays. Functional assays include testing responses to mitogens, which are substances that stimulate replication or proliferation of T and B cells. Common mitogens include phytohemagglutinin (PHA) and concanavalin A (Con A), with larger responses indicating more effective function. Natural killer cell activity (or cytotoxicity) is assessed by measuring the ability of natural killer cells to lyse target cells from known tumor cell lines.

8.02.3.4.1 Regulation of immune function

Both the HPA and sympathoadrenal pathways are involved in immune regulation (Besedovsky & Del Rey, 1996). There are receptors in the cytoplasm of lymphocytes for cortisol, and glucocorticoids suppress the activation of circulating lymphocytes and inhibit production of cytokines (Chrousos, 1995). The HPA plays a major role in the regulation of inflammation, and corticosteroids have long been used as anti-inflammatory agents. In addition, stress-induced production of CRF by the hypothalamus has been shown to reduce T-cell proliferation in response to mitogens independently of adrenal mechanisms (Jain et al., 1991). The sympathetic nervous system innervates immune organs such as the spleen and lymph nodes, and there are adrenergic receptors on circulating lymphocytes. Many of the immune responses to acute stressors are similar to those elicited by injection of epinephrine. It has been argued that sympathetic stimulation may lead to contraction of smooth muscle in the spleen which results in extrusion of lymphocytes into the circulation. Alternatively, the sympathetic nervous system may inhibit production of the cytokine interleukin-2 by helper T cells. Catecholamines also modulate natural killer cell activity.

In many studies of the stress process, it is not possible to determine whether HPA or sympathoadrenal pathways (or both) are responsible for stress-induced changes in immune function. However, there are striking examples of chronic increases in corticosteroid activity being maintained with behavioral stressors in the absence of changes in immune activity (Klein et al., 1992). In addition, alterations of immune function may occur in acute settings before changes in circulating corticosteroid concentrations have evolved. In these cases, sympathoadrenal activity is almost certainly responsible for regulating immune function.

The brain and immune system engage in a two-way dialogue, and the flow of information and control is not simply from the central nervous system to the periphery. Cytokines such as interleukin-1 are released during immune activation and mediate the host's response to infection and inflammation. Cytokines also act centrally, affecting neural growth and repair, stimulating sickness behaviors such as reduced social exploration, food intake and weight loss, and in addition disturbing cognitive functioning (Aubert, Vega, Dantzer, & Goodall, 1995). Dantzer and Kelley (1989) have argued that many of the nonspecific symptoms of sickness and behavioral responses to infectious illness are mediated by immune products, helping to coordinate the central and peripheral responses to infection.

8.02.3.4.2 Acute stress-induced immune responses

A number of studies of cellular immune responses to acute challenges such as problem solving and public speaking have been reported. Among the most consistent effects are an increase in the number of circulating CD8+ and natural killer cells, and reductions in mitogen-induced lymphocyte proliferation (Herbert et al., 1994). Changes in natural killer cell activity have been variable, with increases in cytotocity in some studies and inhibition in others (Bachen et al., 1992; Gerritsen, Heijnen, Weigant, Bermond, & Frijda, 1996). In a particularly striking set of studies, Kiecolt-Glasser et al. (1993) assessed newly-wed couples during a discussion of martial problems, and analyzed neuroendocrine and immune functions from blood samples. They showed that those who manifest critical interpersonal behaviors produced greater decrements than did other couples in natural killer cell activity and mitogen-induced lymphocyte proliferation.

The evidence that these responses are related to sympathoadrenal pathways is strong. The magnitude of immune response has been shown to correlate with the magnitude of cardiovascular reactions (Herbert et al., 1994). Furthermore, many of these responses can be attenuated by the blockade of adrenergic pathways with pharmacological agents (Bachen et al., 1995; Benschop et al., 1994). In contrast with work on cell-mediated effects, studies of acute changes in immunoglobulins have been very limited, although some investigation of IgA concentration in the saliva have been carried out (Herbert & Cohen, 1993b). Immunoglobulins have long half-lives, and salivary IgA may be influenced by saliva flow rate, making interpretation difficult.

8.02.3.4.3 Chronic changes in immune function

There is an extensive literature in animals demonstrating the impact of chronic stressors on immune function such as mitogen-induced lymphocyte proliferation (Coe, 1993; Line et al., 1996). It appears that these effects are ameliorated by social affiliation, which may be an analogue of social support (Cohen, Kaplan, Cunnick, Manuck, & Rabin, 1992). In humans, some of the changes in immune function associated with long-term threats are similar to those observed with acute challenges. Thus a reduction in mitogen-induced lymphocyte proliferation to PHA has been recorded in caregivers for demented patients, bereaved people, and in couples experiencing severe disruption of marital relationships leading to separation or divorce (Herbert & Cohen, 1993b; Kiecolt-Glaser, Malarkey, Cacioppo, & Glaser, 1994). The effects are rather persistent, with deficits being recorded over several years, and responses may be associated with depression (Herbert & Cohen, 1993a). Changes in the number of helper T-cells and cytotoxic-suppressor cells have been inconsistent, with modifications being recorded in some studies but not others.

One important difference from acute reactions is that instead of an increase in natural killer cell number, a reduction has generally been observed with chronic stressors (Castle, Wilkins, Heck, Tanzy, & Fahey, 1995). In addition, natural killer cell cytotoxicity is suppressed. The reason for these differences from the responses to acute stressors is unclear, but immune parameters are influenced by lifestyle variables such as smoking, exercise, and intake of dietary fat and vitamins. These variables are not controlled in naturalistic studies, but may be modified among individuals enduring chronic threats, so affecting the immune responses that are recorded. In addition, the pattern of hormonal reaction may alter with long-term threat, and also has a bearing on immune competence.

One interesting study of innate immune responses was published by Bosch et al., (1996), who assessed the aggregation of streptococcal bacteria in the saliva of students under normal conditions and then prior to an academic examination. Bacterial aggregation was reduced in the pre-exam period, suggesting that the saliva was less effective in preventing bacterial adhesion to oral surfaces, and defending against the early stages of infection. As far as immunoglobulins are concerned, studies have been carried out relating nonspecific salivary IgA to mood fluctuations (Evans, Bristow, Hucklebridge, Clow, & Walters, 1993). No differences in the production of IgM or IgG in adults exposed to severe long-term threat and control were recorded by McKinnon, Weisse, Reynolds, Bowles, and Baum (1989), while another study recorded associations with daily hassles (Jabaaij, Benschop, et al., 1993a). Rather consistent changes in antigen-specific salivary IgA and serum antibody response have also been recorded in studies by Stone et al., (1994). Subjects consumed a capsule containing a novel oral antigen on a daily basis, so the IgA antibody response was elicited in a way that might be analogous to invasion by a novel virus. Over several weeks, desirable daily events were associated with elevated IgA antibody production, while undesirable events led to a suppressed antibody response.

8.02.3.4.4 Functional significance of stress-induced immune modulation

An issue that arises in the investigation of immune responses is whether the changes are of clinical significance, or are so small as to be solely of academic interest. Many alterations in immune function will only affect health if an invading pathogen is present, so a short-term change in function may have few consequences if it does not coincide with exposure. There are now studies that have addressed functional significance more directly. One of the first models to be used was the response to latent viruses that remain within the host undetected unless deficits in immune control allow replication to increase. Large antibody titers to latent herpes viruses such as herpes simplex or Epstein-Barr virus indicate poor control by the cellular immune system over these pathogens. Reports by Kiecolt-Glaser, Glaser and colleagues have shown that antibody titers are elevated as part of the stress response (Kiecolt-Glaser et al., 1994).

A second approach has been to assess responses to nonpathogenic antigens, since studying the immune response to experimental infection is rarely ethical. Vaccination provides a useful model, but results to date have been inconclusive. One study of responses to influence of vaccine showed that psychological distress was associated with poor lymphocyte proliferative responses, while a second study showed no significant effects. Poor immune responses to hepatitis B vaccines have been elicited by acute or chronic stressors in some investigations but not in others (Glaser et al., 1992, Jabaaij et al., 1996). Results evidently depend critically on the timing of measures of the immune response, and on the size of the vaccination dose.

A third method that shows considerable promise relates to wound healing. Cellular immunity plays an important role, since cytokines such as interleukin-1 and tumor necrosis factor help to protect against infection and repair the damaged tissue. An investigation of caregivers for Alzheimer victims and matched controls has been published (Kiecolt-Glaser, Marucha, Malarkey, Mercado, & Glaser, 1995). Participants were given a punch biopsy to create a standard small wound on the forearm, and the rate of healing was assessed in the two groups. Wound healing was delayed among care-givers, and cytokine responses were impaired. This approach provides direct evidence for stress-induced suppression of immune defense being significant for health, and may be relevant to studies of psychosocial influences over recovery from surgery.

8.02.3.5 Adaptive or Destructive?

It has been argued since the earliest scientific investigations that the physiological activation seen under conditions of behavioral stress is an adaptive response. Its "purpose" is to prepare the organism for vigorous physical work such as might be called upon with fighting or escaping from danger. Thus, stored energy supplies are mobilized to feed working muscle, clotting processes are stimulated to prevent blood loss from wounds, and vegetative functions that are not essential for short-term activity are suppressed. Unfortunately, this phylogenetically primitive psychophysiological response is stimulated in humans under circumstances that do not call for vigorous exercise, and may therefore become destructive.

There are, however, features of psychophysiological responses that are puzzling from this perspective. They include the inhibition of inflammatory responses, the suppression of cell-mediated immunity, and the promotion of fluid loss through inhibition of the antidiuretic hormone vasopressin. How can the hypothesis that the response pattern is adaptive be reconciled with the evidence that some of the body's major defense systems are disrupted? How could such an organization of physiological responses survive the pressures of evolution?

Various explanations of this apparent anomaly have been put forward. One possibility is that suppression of immune responses is adaptive in directing energy to more pressing needs. Maier, Watkin, and Fleshner (1994) have argued that the production of acute phase responses, which include substantial cellular proliferation plus increases in body temperature, requires an increment in caloric energy production of at least 10%. Such responses might be difficult to sustain in the presence of the simultaneous demands of vigorous exercise. A second possibility developed by Besedovksy and Del Rey (1996) is that it may be adaptive for a species if on occasion immune systems fail and lead to the death of an individual, since this may prevent transmission of pathogens to conspecifics. This active negative self-selection may sacrifice the individual to ensure survival of other members of the population.

Another view that has gained widespread acceptance is that the role of the HPA axis is not to stimulate defense reactions, but rather to act as a regulatory mechanism and a restraint on other defenses. Munck, Guyre, and Holbrook (1984) have proposed that glucocorticoids play a central role in preventing the overshoot of inflammatory, immune, and metabolic responses that might otherwise take place when the organism is challenged. They suggest, for example, that in the absence of glucocorticoid counter-control, high levels of insulin might cause dangerous hypoglycemia, and that the suppression of vasopressin prevents excessive fluid retention. Chrousos (1995) has extended this perspective by pointing out that corticosteroid release may protect against susceptibility to autoimmune diseases. These are diseases in which the body's own antibodies cause inflammation and tissue destruction, and include rheumatoid arthritis, pernicious anemia and various types of thyroid dysfunction. In the absence of sustained control over immune responses by corticosteroids, risk might be increased.

8.02.4 THE NATURE OF PSYCHOSOCIAL DEMANDS

It will be apparent from the discussion thus far that a wide range of physiological responses are mobilized as part of the stress response. The question arises of what types of psychosocial demand stimulate these responses, and what characteristics of stressors are particularly relevant.

8.02.4.1 Life Events, Chronic Stressors, and Daily Hassles

Adverse experiences that have an impact on psychophysiological responses are conveniently divided into acute events that can be pinpointed in time and cause substantial disruption to life, chronic adverse social factors that may continue for months or even years, and less severe day-to-day sources of irritation (daily hassles). All three types of phenomenon have been associated with psychophysiological responses and subsequent health risk. Among the acute events, earthquakes and other natural disasters may be followed by elevations in health problems and mortality (e.g., Adams & Adams, 1984, Trevisan et al., 1992). Bereavement through death of a partner leads to responses such as immune down-regulation and an increase in all-cause mortality risk (Jones, 1987), while other life events have been associated with problems such as premature delivery for pregnant women (Nordentoft, Lou, & Hanson, 1996). Chronic stressors, such as living in the presence of loud ambient noise, crowding, unemployment, or caring for dementing relatives, also have effects on psychophysiological processes, and in some cases on mortality (Evans, Hygge, & Bullinger, 1995; Kiecolt-Glaser et al., 1994; Morris, Cook, & Shaper, 1994). Daily hassles have been linked with fluctuations in salivary cortisol levels, blood pressure, and IgA (Steptoe et al., 1996; Stone et al., 1994; Van Eck et al., 1996).

The quantification of psychosocial demands has been discussed and criticized extensively elsewhere (Cohen et al., 1995b). One of the issues to emerge is that many standard measures of life events may misrepresent the impact of adverse experiences by failing to be comprehensive (Turner, Wheaton, & Lloyd, 1995). If certain types of events are more common in one sector of society than another, then failure to include such experiences in the assessment instrument would lead to underestimation of exposure. This may account for the observation that has repeatedly been made in the literature that young adults experience more stressful events than older people; this is because many life event measures target events such as pregnancy, marriage, and so forth at the expense of the infirmities and loss of capacity that are more common among the elderly. Aneshensel (1992) has argued that life event research may neglect the problems of ordinary social life and that the latter show strong gradients with socioeconomic status that may not be apparent for acute events. Although it is convenient to distinguish acute events from chronic stressors, in reality the classification is far from clear cut. Many important life events have long-term ramifications that either precede the actual event (such as discord leading up to a marital separation), or last well beyond the incident itself. Single acute events may show a sustained capacity to elicit physiological activation through repetitive intrusive memories and other cognitive transformations.

Rather little is known about the extent to which the impact of acute events or chronic severe stressors is mediated through daily hassles. An event such as the death of a spouse is distressing in itself, but may also lead to numerous petty difficulties in financial and legal matters, the practicalities of living, and in social life. An interesting analysis of this issue was described by Pillow, Zautra, and Sandler (1996), who investigated the links between major threats such as death of a spouse, divorce, or having a child with chronic illness, daily hassles, and psychological distress. Different links between hassles and the various types of major threat were observed. The impact of divorce on psychological distress was mediated almost entirely through daily hassles, while the impact of a serious childhood illness was independent of daily hassle levels. The associations between bereavement and distress were partly direct, and partly mediated through an increase in daily hassle levels.

These issues have implications for systematic investigations of psychosocial factors in health risk. One of the major problems encountered in the study of physical illness is the "independence" of events from the prodromata of clinical illness. Many cross-sectional or retrospective studies of psychosocial factors examine life events or chronic stressors in case-controlled designs, comparing, for example, women who show a recurrence of breast cancer with nonrecurrence (Ramirez et al., 1989), or insulin-dependent diabetics and their siblings (Robinson & Fuller, 1985). Inferences concerning the causal sequence depend critically on the timing of adverse life experiences. But many threatening events such as being sacked from a job, or a breakdown in important relationships, may be the culmination of a series of hassles, some of which may have preceded physical pathology, or have even been caused by early symptoms and limitations in capacity brought on by the medical condition itself.

8.02.4.2 Characteristics of Psychosocial Demands

The arguments outlined in earlier sections indicate that psychophysiological responses are not uniform across situations, but vary with the nature of demands. Some of the broad dimensions that appear relevant are described in this section.

8.02.4.2.1 Novelty, familiarity, and predictability

Psychophysiological responses tend to be more intense when animals or humans are placed in unfamiliar situations and confronted with novel demands. This was strikingly illustrated by Mason (1975) who found that the neuroendocrine reactions elicited in primates were as great when animals were placed in the experimental situation for the first time, as they were to any subsequent "stressors." The neuroendocrine and autonomic reactions in people learning new dangerous skills such as parachuting also typically diminish rapidly with repeated exposure.

The reduction in psychophysiological responsivity with familiarity may be due to several factors. Natelson et al. (1988) have argued that adaptation in physiological stress responses is similar to the process of sensory habituation. Many biological systems show reduced responsivity over time, with alterations in biosynthesis, storage, secretion and re-uptake capacity, modulation of receptor sensitivity, and the institution of counter-regulatory feedback mechanisms. Familiar conditions may also elicit smaller psychophysiological responses because they become predictable. Psychophysiological responses are more pronounced in unpredictable conditions, even if the duration and intensity of stimulation is the same as that in predictable conditions (Abbott, Schoen, & Badia, 1984). To take just a few examples, rat studies have shown that corticosteroid responses are enhanced and the proliferative capacity of lymphocytes is suppressed by unpredictable as opposed to predictable stressors (De Boer, Van der Gugten, & Slangen, 1989; Mormede, Dantzer, Michaud, Kelley, & Le Moal, 1988), while in humans, Zakowski, Hall, and Baum (1992) found that lymphocyte proliferative responses to Con A were impaired to a greater extent with unpredictable stressors.

8.02.4.2.2 Control and lack of control

Behavioral control over psychosocial demands can be defined as the possibility of being able to take actions that prevent, terminate, or modify aversive stimulation. Lack of control implies that such actions are not available to the individual because of the prevailing circumstances, or because the actions are not in the behavioral repertoire. In the context of psychophysiological stress responses, perceived control, or the perception that actions can be taken, may be as important as actual control.

There is ample evidence from acute studies in animals that simple forms of behavioral control such as pressing a lever to avoid or escape shock are associated with smaller psychophysiological responses than equivalent uncontrollable stimulation. Uncontrollable conditions elicit greater corticosterone and catecholamine responses, an increased tendency to gastric lesions, a decrease in natural killer cell cytotoxic activity and mitogen-induced lymphocyte proliferation, and greater weight loss (Steptoe & Appels, 1989). In humans, diminution in blood pressure, heart rate, and cortisol responses have been recorded with controllable demands as opposed to equivalent demands that are not controllable.

However, the beneficial effects of control are limited to circumstances in which the behavioral responses are relatively easy to carry out. When contingencies are more complex or when behavioral tasks are difficult, physiological responses may be enhanced. This was neatly demonstrated in the study of gastric lesions in rats administered escapable or yoked inescapable electric shocks (Tsuda, Tanaka, Nishikawa, & Hirai, 1983). When the behavioral response was simple, animals in the uncontrollable condition showed greater ulceration than those in the controllable group. But with complex contingencies, the situation reversed. In humans, it is known that increasing task difficulty is associated with greater blood pressure and sympathetic nervous system activity (Callister, Suwarno, & Seals, 1992). When the tasks that must be carried out to maintain control over aversive stimulation are difficult and require considerable effort, psychophysiological responses may be greater than in uncontrollable conditions (Bongard, Hodapp, Frisch, & Lennartz, 1994). Even the perception that the person has chosen difficult tasks to perform may elicit heightened cardiovascular responses (Sherwood, Royal, & Light, 1993). However, it should be emphasized that in humans, the negative consequences of effortful control have largely been recorded during acute laboratory studies. Whether effects are sufficient to offset the benefits of perceived control in clinical and naturalistic settings remains unknown.

8.02.4.3 Work Characteristics, Control, and Psychophysiological Responses

For people in employment, work occupies a considerable portion of waking life. It is scarcely surprising therefore that the work characteristics associated with ill-health have been extensively studied. Various types of pathology such as hypertension and peptic ulcer are more prevalent in people in certain demanding occupations, although it is often difficult to disentangle psychophysiological processes from variations in lifestyle and health behavior (Cobb & Rose, 1973). Work may also lead to increases in catecholamines and blood pressure, notwithstanding the points made in Section 8.02.2.2.3 about the role of physical activity that remain pertinent to these investigations.

Much research on the health risks of work has been oriented around the demand-control model of job strain put forward by Karasek (1979). This proposes that risks to health are particularly great when work is characterized by high demands or work load coupled with low control or autonomy. The model therefore points to control as being an important element of psychosocial demand. A substantial literature has accumulated suggesting that high demand/low control jobs are associated with increased risk of coronary artery disease and high blood pressure (Schnall, Landsbergis, & Baker, 1994). The data are not all consistent, and other factors such as social support at work and psychological traits also need to be taken into account. A study from the author's laboratory suggested that perceptions of job strain and a disposition to high physiological stress reactivity interact in determining elevated blood pressure at work (Steptoe, Roy, Evans, & Snashall, 1995). A group of healthy young men working as fire-fighters were classified on the basis of job strain and their blood pressure reactivity to standardized mental stress tests. Eighteen months later, blood pressure was monitored during a work shift and an equivalent period of leisure using automated ambulatory apparatus. Neither high job strain nor physiological reactivity in isolation predicted blood pressure at work, but men who displayed both characteristics had elevated blood pressure during the later hours of their work shifts.

8.02.4.4 Concurrent Stressors

Adverse life experiences do not occur in isolation, but are superimposed on a background of hassles or chronic stressors. An issue that is poorly understood is the role of concurrent stressors in determining levels of psychophysiological activity. It might be assumed that if people are already under pressure because of other problems in their lives, then the reactions to fresh threats would be heightened. Alternatively, it is possible that new demands might act as distractors from concurrent difficulties, dampening the intensity of responses.

Cardiovascular responses to mental stress were inversely related to recent life events in a study of adolescents (Boyce & Chesterman, 1990), and beta-adrenergic receptor density was lower among homeless people who had experienced severe life events over the past six months (Dimsdale, Mills, Paterson, Ziegler, & Dillon, 1994). Other studies have shown that high occupational demands are associated with reduced blood pressure responses to acute mental stress tests (Schaubroeck & Ganster, 1993). These reports are consistent with the notion that concurrent stressors dampen physiological responses to fresh challenges. But other work points to the opposite conclusion, with the chronic stress of crowding and high levels of recent hassles being associated with elevated cardiovascular reactions and reduced antibody formation to hepatitis B vaccination (Fleming, Baum, Davidson, Rectanus, & McArdle, 1987; Jabaaij, Grosheide et al., 1993b). It is not certain what factors determine whether concurrent stressors enhance or inhibit psychophysiological responsivity.

8.02.5 RESISTANCE AND VULNERABILITY FACTORS

The other side of the model outlined in Figure 1 concerns the personal characteristics, social resources, and experiential and biological factors that serve to increase or decrease the ability of people to adapt effectively to psychosocial demands. These factors will be outlined in this section, focusing particularly on the evidence for influence over psychophysiological processes. The inclusion of both resistance and vulnerability factors reflects the presumption that some characteristics are protective, while others are potentially damaging.

Perhaps the ideal type of evidence is from studies in which individuals or groups who differ on a putative resistance or vulnerability factor are exposed to identical demands. Any difference in psychophysiological response or health risk would indicate that the factor in question was indeed operative. Within this framework, the resistance or vulnerability factors might exert a "buffering" effect, being operative at high but not low levels of psychosocial demand. Alternatively, they might exert "direct" effects, influencing responses irrespective of the level of demand. Many resistance and vulnerability factors may influence psychophysiological variables through their associations with different types of behavioral and cognitive coping response.

The vulnerability factors discussed in this section are those related to psychophysiological responses in general. The factors that may predispose people to particular types of health problem are considered in Section 8.02.6.

8.02.5.1 Personality and Behavior Patterns

A number of personality factors have been postulated as relevant to stress vulnerability and resistance. Some have been linked to risk for specific disorders (the best known case being Type A coronary-prone behavior), while others are thought to affect general vulnerability to psychosocial demands. There are several processes through which personality might influence psychophysiological responses, and these have been described by Bolger and Zuckerman (1995). First, personality factors or habitual ways of behaving might affect exposure to demands, increasing or decreasing the experience of potential threats by influencing social, vocational, and recreational activities. For instance, a person high in extroversion may have a very different experience of life than one who is introverted. Second, personality factors may affect the appraisal of situations, and whether or not they are perceived as threatening, challenging, irrelevant, exciting, controllable, and so on. Neuroticism and hostility come to mind as exemplars of this process. Third, personality can influence the individual's choice of coping responses. For example, an individual with high internal locus of control may launch into efforts at active problem-solving more readily than someone with external beliefs.

Finally, personality may have an impact on the effectiveness of coping responses. A person with high hostility scores may mobilize social support in an effort to cope, but alienate his or her social contacts with abrasive behavior. Thus far, there are rather few studies that have been able to tease out these different modes of action. Intriguing findings have been described for a number of personality and behavioral patterns including locus of control (Parkes, 1984), sense of coherence and conscientiousness (Friedman et al., 1995). The concept of the hardy personality developed by Kobasa has attracted considerable attention, but has also been criticized on conceptual and empirical grounds (Funk, 1992; Kobasa, Maddi, Puccetti, & Zola, 1985). This review is therefore confined to four areas of research into personality and behavioral patterns that appear especially relevant to psychophysiological processes.

8.02.5.1.1 Disease-prone personality and negative affectivity

The notion that a constellation of personality characteristics may put people at higher risk for all manner of diseases was proposed by Friedman and Booth-Kewley (1987). They described meta-analyses in which high levels of anxiety, neuroticism, depression, anger, and hostility emerged as features linked with a range of pathologies including coronary heart disease, bronchial asthma, peptic ulcer, rheumatoid arthritis, and headache. It was postulated that a person with these characteristics was predisposed to developing physical illness, but that the nature of the illness would depend on biological factors such as genetic risk.

This position can be criticized on three main grounds. First, many of the studies used to support this proposition are cross-sectional or retrospective in nature. It cannot be assumed that the psychological characteristics displayed by someone with manifest disease were present prior to diagnosis, or are present among people with similar medical conditions who have not been diagnosed (the "clinical iceberg"). Many of the illnesses discussed by Friedman and Booth-Kewley lead to functional limitations, pain, and impaired quality of life. It is not surprising that individuals with these problems score higher on measures of anxiety, depression, and anger or irritation than healthy people. In some cases such as hypertension, it is known that diagnosed cases and awareness of the problem are associated with increased psychological distress and neuroendocrine activation independently of blood pressure levels (Rostrup, Mundal, Westheim, & Eide, 1991).

Second, the constellation of factors thought to reflect disease-prone personality overlaps strikingly with negative affectivity. Negative affectivity is a tendency to pervasive dysphoria and low mood, and has been found to influence reports of social support, life events, and symptoms, and to affect health service utilization (Watson & Pennebaker, 1989). It is frequently indexed by measures such as neuroticism, so is difficult to distinguish operationally from a personality trait in cross-sectional studies. Negative affectivity is a mediator of associations between stressors and affective responses, and may consequently contribute to the correlation between disease and personality as well.

The third reason for reservations about the disease-prone personality is that it agglomerates a range of characteristics, each of which may have distinct associations with health risk and psychophysiological responses. To group factors such as depression, anxiety, and hostility together loses the potential for refining the role of psychosocial factors.

8.02.5.1.2 Anger and hostility

The constructs of anger and hostility illustrate this point very well. There has been great interest in the role of these factors in physical health. However, there are many different types of measure and experience that fall within this area, and not all may be relevant to health risk. Thus anger as an emotional state or trait can be separated from hostility, which is generally regarded as a broader construct involving cognitive and behavioral factors. Cynical hostility, for example, is centered on beliefs that others are motivated by selfish concerns, and is a dimension tapped by the Cook and Medley Hostility Scale. These characteristics can in turn be distinguished from the expression of anger (a behavioral response) and from overt aggression.

Space prevents more than a brief summary of the literature relating anger and hostility to physical health and psychophysiological processes. Interest has chiefly focused on cardiovascular disorders. Although the literature is not all consistent, meta-analyses indicate that coronary heart disease and its manifestations such as myocardial infarction are positively associated with overt hostility (Miller, Smith, Turner, Guijarro, & Hallett, 1996). There is limited evidence that hostility also predicts all-cause mortality and by implication health in general. A different pattern is found for high blood pressure, which is associated with low levels of anger expression, particularly among people who are not aware of their blood pressure level (Jorgensen et al., 1996).

These effects are not of course necessarily mediated through psychophysiological pathways, since hostility has also been associated with poor health habits such as lack of exercise and drinking and driving (Leiker & Harley, 1988). However, a number of investigators have shown that hostility is positively related to cardiovascular reactions to mental stress, particularly under conditions of harassment and provocation (Suls & Wan, 1993). Hostility is also positively correlated with cortisol excretion during the day, and with blood platelet activation, an early marker of thrombotic processes (Markovitz, Matthews, Kriss, & Smitherman, 1996; Pope & Smith, 1991). It is reasonable to assume, therefore, that anger and hostility are vulnerability factors in psychophysiological processes and disease.

8.02.5.1.3 Depression, pessimism, and optimism

People with serious illnesses frequently experience depression. Clinically, it is commonly observed that people suffering from painful conditions such as chronic back pain or rheumatoid arthritis are at least mildly depressed for a great deal of the time. Depression is also associated with nonpainful but restrictive conditions such as bronchial asthma and various cardiomyopathies. Herbert and Cohen (1993a) have reported a meta-analysis of studies linking depression with immune function, and conclude that depressed people generally exhibit lower mitogen-induced lymphocyte proliferation, natural killer cell activity, and smaller numbers of circulating helper T-cells than do comparison groups. Studies of patients following myocardial infarction indicate that depressed individuals are at high risk for future complications and early mortality independent of cardiological variables (Frasure-Smith, Lespérance, & Talajic, 1993), and pessimism as a trait has been shown to predict future mortality in at least one longitudinal study (Peterson, Seligman, & Vaillant, 1988).

These associations raise the question of whether psychiatric disorder of an affective nature increases risk of physical illness. There has been speculation on this topic for many decades, and recent years have seen the publication of several convincing systematic studies. For example, Huppert and Whittington (1995) used data from the Health and Lifestyle Survey to show that elevated scores on the General Health Questionnaire predicted mortality over a seven-year follow-up period independently of age, diagnosed physical disorder at the start, social class, and smoking. A more rigorous interview-based measure of depression was used in a study of first-degree relatives of depressed patients and controls (Moldin, et al., 1993). People classified as having experienced clinical depression at some time in their lives were at increased risk for headache, skin infection, respiratory illness, diabetes, and low blood pressure, after controlling for age, sex, and alcohol use.

In a larger study of people with diagnosed anxiety and depressive disorder in Sweden, risk of death from coronary heart disease was increased among men but not women (Allgulander, 1994). Unfortunately, interpretation of studies of this kind is problematic, since utilization of healthcare services may be different among people who are distressed or depressed, leading in some circumstances to an increased likelihood of diagnosis of conditions that might otherwise go unnoticed. Psychological disturbance may be a product of early subclinical physical illness, and not predate health problems. Patterns of health behavior such as exercise and food choice also vary with mental health, and may contribute to increased risk of disease.

The other side of the coin is optimism, which has been defined by Scheler and Carver (1992) as a set of global expectancies in which people generally experience good as opposed to bad outcomes in life. Optimism as measured, for example, by the Life Orientation Test, has been associated with favorable adaptation to cardiac surgery, lower distress among women with breast cancer and HIV positive men, and fewer psychological problems following unsuccessful medical interventions (e.g., Carver et al., 1993; Taylor et al., 1992). An optimistic disposition appears to be associated with the use of adaptive coping strategies in the face of threat, such as planning and positive reinterpretation, with low levels of cognitive avoidance. In this respect, optimism would appear to fulfill the criteria for a general resistance factor.

8.02.5.1.4 Emotional inhibition

One of the key concepts underlying the psychodynamic tradition of psychosomatics is that physical disorders might emerge through repression of neurotic conflicts. From this, the idea developed that people suffering from various physical complaints might be emotionally repressed or inhibited. A more modern development of this theme is the construct of alexithymia, a difficulty in accessing feelings and bodily sensations and in relating to emotional experiences (Sifneos, 1973). The hypothesis that the inhibition of emotion is potentially damaging can be supported without accepting all the intellectual penumbra of psychodynamic thought. Openly discussing emotionally-charged events may facilitate emotional processing, may help give meaning to distressing experiences, and may allow for social comparison and input of information and advice from others.

Several different methods of operationalizing the inhibition of emotion have been developed in the research literature (Pennebaker, 1995). The method developed by Weinberger and coworkers involves measuring anxiety and social desirability so as to identify people who report low anxiety together with high social desirability scores (Weinberger, Schwartz, & Davidson, 1979). The rationale is that people with a "repressive coping style" fail to acknowledge emotional distress (hence having low anxiety) but also desire social approval. Weinberger et al., found that students with repressive coping styles showed greater autonomic responses to a task than did genuinely low anxious individuals. This finding has been replicated in other studies, although not entirely consistently. For example, antibody titers to Epstein-Barr virus antigen were found to be raised among students with high anxiety plus high social desirability scores by Esterling, Antoni, Kumar, and Schneiderman (1993), and not among repressors.

Simpler measures of emotional expression are also negatively associated with physiological responses to challenge, a pattern that has been identified even in children of three and four years old (Cole, Zahn-Waxler, Fox, Usher, & Welsh, 1996). Anger inhibition may be particularly relevant to the development of hypertension, and has been shown to predict heightened cardiovascular reactions to mental stress tests in people with a family history of high blood pressure (Vögele & Steptoe, 1993). Another approach has been to assess the psychophysiological and health consequences of disclosure of emotionally distressing information. In one study of this kind, students were randomized into writing about very traumatic episodes in their pasts, or essays on neutral topics (Pennebaker, Kiecolt-Glaser, & Glaser, 1988). Cellular immune function appeared to be favorably affected by confronting traumas, with some evidence for a reduction in episodes of minor illness over subsequent weeks. There are other intriguing preliminary findings suggesting that lack of disclosure may have important health consequences. Cole, Kemeny, Taylor, and Visscher (1996) followed a cohort of HIV-negative homosexual men with regular health checks over a five-year period. They found that men who concealed their homosexual identity experienced a high incidence of infectious illnesses such as sinusitis and bronchitis, independent of common health behaviors, negative affect, age, and education. Risk for these types of disorder might be mediated through suppression of immune defense.

8.02.5.2 Social Isolation and Social Support

The influence of social isolation, social integration, and social support on health risk is now well established. A substantial literature on social support and physiological processes has also emerged, and this has been amply reviewed by Uchino, Cacioppo, and Kiecolt-Glaser (1996). Social network refers to the person's web of social relationships and ties, and is typically assessed by measures such as marital status, number of people in the household, number of close friends and relatives, church attendance, and participation in group activities. Composite measures of social networks have been shown to predict mortality in the Alameda County study, Tecumseh, Scandinavian cohorts, and elsewhere (House, Landis, & Umberson, 1988). It is apparent that network measures may include a number of quantitatively different types of social contact, and it is unlikely that all are equally important. Church attendance may bring with it particular attitudes to problems and styles of coping that have little to do with group involvement *per se*, while marriage is much more than having someone close in the social network.

The function of social networks is thought to be to provide social resources and support, and several types of support can be distinguished. They include material or tangible support, such as the provision of assistance with tasks; emotional support, or the availability of someone with whom to share personal problems and from whom to receive comfort and concern; informational support which involves the provision of advice and suggestions about plans of action; and belongingness, or a sense that one is part of a group with similar interests and concerns. Again, not all these elements are equally important across situations. The mother with young children who has recently been left by an errant spouse might benefit particularly from practical support in terms of help with child-care and shopping, and informational support such as legal advice. By contrast, a person worried about being dismissed from their job might especially value emotional support and a feeling that they still belong to their social group.

Social support and strong social networks are not uniformly distributed through the population. Perceived social support from spouses, friends, relatives, and co-workers is greater among people of higher socioeconomic status (Turner & Marino, 1994). In the Whitehall II epidemiological study of British civil servants, satisfaction with practical support was greater in men of higher than lower employment grade (Marmot et al., 1991). Women tend to report higher social support than men from most sources, although ratings of relationships with spouses are frequently less positive. In their studies of the social origins of depression, Brown and Harris (1978) showed that poor spouse/partner support was more frequent among women of low social class with young children at home than it was in other groups. It should of course be recognized that in general, social ties may have many negative consequences, and some of the most potent sources of chronic distress arise from relationships in the family (Burg & Seeman, 1994).

The literature is rather consistent in showing that social networks and social support are associated with favorable cardiovascular function (Uchino et al., 1996). For example, a study of elderly Swedish men found that blood pressure was negatively correlated with degree of anchorage in formal and informal social groups after controlling for social class, marital status, alcohol, smoking, body weight, and physical activity (Hanson, Isacsson, Janzon, Lindell, & Rastam, 1988). A frequently cited follow-up study of Italian nuns from a secluded and close-knit religious order showed that their rise in blood pressure with age was less marked than in the general population, although being a nun has more to it than social integration (Timio et al., 1988). Dressler (1991a, 1991b) has performed an interesting set of studies showing an interaction between chronic life stress and support among black men in southern USA. A subgroup were characterized by "lifestyle incongruity," in that their lifestyle in terms of material goods and status displays exceeded their occupational position. Dressler argued that efforts to maintain such an ostentatious lifestyle in the absence of sufficient funds constituted a source of chronic life stress. He found that blood pressures were indeed higher among men with lifestyle incongruity, but only when they had low levels of social support.

Physiological variables have also been assessed in a series of acute laboratory studies of responses to standardized tasks carried out in the presence of supportive friends. Effects have been somewhat mixed, although there is some evidence that cardiovascular reactions are reduced in the presence of friends (Kamarck, Annunziato, & Amateau, 1995). Evidence concerning neuroendocrine function and social support is less consistent, with several studies showing little effect. Immune data are more compelling in showing that the down-regulation of function elicited by chronic stressors may be ameliorated by support (Baron, Cutrona, Hicklin, Russell, & Lubaroff, 1990; Kiecolt-Glaser et al., 1991).

The results of studies that have attempted to bolster social support but have been rather disappointing to date. For example, Arnetz et al. (1987) randomized unemployed women to control or intervention groups that provided information and engaged in alternative activities. No effect on immune or endocrine function was observed. A very substantial study providing social support to deprived young pregnant women in Latin America failed to find any protective effects on birth outcomes (Villar et. al., 1992). Helgeson and Cohen (1996) have argued that although emotional support groups are desired by patients with cancer, there is little evidence that they are of benefit in terms of psychological well-being or other aspects of adjustment. It is not yet clear that support provided externally will necessarily have comparable effects to support that emerges more naturally from the individual's evolving social world.

8.02.5.3 Prior Experience of Stressful Events

There are distinct schools of thought about whether prior adverse experience helps to strengthen the individual's resistance to later threats, or whether it increases vulnerability. On one side, there is evidence that earlier stressful experiences increase vulnerability to later adverse events. Thus experiences such as disruption of family relationships early in life increase risk for later emotional and behavioral problems (Wadsworth, Maclean, Kuh, & Rogers, 1990). In work on life events and depression, Brown and Harris (1978) found that women who had as children experienced the loss of their own mothers through death, ran a high risk of developing depression in adult life in the face of negative life events. Adverse effects are by no means inevitable, since the impact of early stressful experiences is ameliorated by temperamental factors and coping style (Garbarino, Kostelny, & Dubrow, 1991). Cortisol responses to stressful situations are smaller among infants with more secure attachments (Nachmias, Gunnar, Mangelsdorf, Parritz, & Buss, 1996). Animal studies have shown that early social isolation leads to increased HPA output, reduced lymphocyte activation by mitogens, and an elevation of central norepinephrine turnover (Suomi, 1991). The enhancement of psychophysiological responses arising from disruption of early development may increase vulnerability to later disease. Prenatal factors may also be significant. For example, the exposure of pregnant rats to behavioral stress has been shown to influence the immune function of their offspring (Klein & Rager, 1995), and influences on later neuroendocrine function have been described as well.

On the other side, prior experience may mitigate the effects of later aversive stimulation. Thus early handling in laboratory animals produces more rapid adaptation to avoidance conditioning, smaller adrenal responses to chronic stress, and enhanced antibody responses to experimental infections (Solomon, Levine, & Kraft, 1968). Dienstbier (1989) has argued that prior stressful experiences lead to "physiological toughening," and more effective adaptation to later challenges. A direct test of this model was described by Norris and Murrell (1988) who examined the impact of a natural disaster (serious flooding) on anxiety symptoms. It was found that older adults who had experienced similar disasters earlier in their lives showed better adaptation than did those who lacked prior experience.

These discrepant findings can probably be reconciled through consideration of the specific adverse events experienced in the past and current demands on the individual. Previous exposure to a particular threat (such as a natural disaster) might indeed improve adaptation, since the sequence of events will be more familiar and less unpredictable than before, and strategies for coping may already have evolved. Other types of threatening experience may disrupt developmental trajectories, impair self-esteem and reduce the individual's social resources, leading to heightened responsivity to later events.

8.02.6 PATHWAYS TO DISEASE—PREDISPOSING FACTORS

Thus far, factors have been described that influence the magnitude and duration of psychophysiological responses in a general fashion. However, as well as establishing credible biological pathways, models of psychophysiological processes in disease must account for individual differences. Why is it that groups who suffer from "stress-related" pathology often do not appear to have more stressful lives than those who remain healthy? How is it that two people may have similar life experiences, yet one becomes ill while the other remains healthy? Why, in the face of chronic stressors, do some people succumb to infectious illness while others show increases in blood pressure and the development of hypertension?

Faced with these issues, it has been traditional in psychophysiological models to invoke "biological vulnerability" as an explanation. People will succumb to the pathologies to which they are most vulnerable, depending on their *locus minoris resistentiae*. Thus an individual prone to coronary artery disease will show accelerated atherogenesis with adverse life experience, while another susceptible through biological factors to muscular contraction will be at increased risk for headache or muscular skeletal pain. Still another person may be physically robust, but prone to anxiety disorders.

This model may account superficially for individual differences, but unless it is properly characterized it has little explanatory power. The problem is that unless biological vulnerability is defined *a priori* with clear measurable markers, then there is the danger that vulnerabilities are identified after the event, and that reasoning becomes circular. Fortunately, there has been progress over recent years in delineating predisposing factors. Some of these help account for why one person becomes ill and another does not, while others explain why individuals succumb to particular forms of ill-health.

8.02.6.1 Nutrition and Exercise

Nutritional deficits in early life affect later functioning of the immune system even after proper nutrition has been reinstated. A persistent alteration in phagocytosis and an accelerated decline in cell-mediated immunity have been described (Dutz, Kohout, Rossipal, & Vessal, 1976). Serum immunoglobulins appear relatively unaffected by malnutrition through protein and energy deficits, but secretory IgA responses are reduced and may enhance the risk of succumbing to viral infection. Among elderly people, subtle and often undetected micronutrient deficiencies lead to reductions in lymphocyte function and natural killer cell activity (Chandra, 1989). Other aspects of nutrition such as the consumption of saturated fats, salt, and fruit and vegetables are of clear importance as risk factors in disease. Thus nutritional profiles may have a profound influence on the extent to which psychophysiological responses will have clinical consequences in terms of disease risk.

Regular physical activity and physical fitness may potentially be protective. A substantial number of studies have assessed associations between fitness or regular activity and psychophysiological stress responsivity. Although by no means consistent, investigators have shown that blood pressure and catecholamine stress responses are smaller among fit or more active individuals (Seraganian, 1993). However, cross-sectional differences may be due to selection factors or other aspects of the lifestyle of sedentary and active people. Efforts have therefore been made to assess psychophysiological responsivity to mental stress before and after exercise training. Again the results have been very mixed, with reductions in stress responsivity with physical training emerging in some studies but not others (De Geus, Van Doornen, & Orlebeke, 1993; Rogers, Probst, Gruber, Berger, & Boone, 1996). The explanation of these discrepancies is not clear, so the extent to which psychophysiological mechanisms are moderated by regular physical activity and fitness is uncertain. Field studies certainly suggest that fitness is protective. For example, Brown (1991) found that in a sample of students, adverse life events over the past year were associated with psychological distress and self-reported illness level. However, both illness rates and healthcare utilization were lower in those who had experienced life events but were also physically fit, as opposed to the unfit. Results of this kind indicate that further investigation of the influence of regular activity and fitness on psychophysiological processes and disease is warranted.

8.02.6.2 Advanced Age

Many of the medical disorders investigated in health psychology are more common in older than younger adults, including coronary artery disease, rheumatoid arthritis, high blood pressure, and various cancers. The issue of aging is becoming increasingly important to an understanding of psychosocial contributions to disease risk (Schaie, Blazer, & House, 1992). The nature of psychosocial demands changes with age. Heckhausen and Schulz (1995) have argued that later years are characterized by increasing exposure to events over which the individual has little control, including bereavement, health problems, the reduced economic power associated with retirement, and diminution in social networks due to death and changing roles. People who appear to age more successfully may adapt by lowering their evaluation of the importance of areas of life over which they lose control (Brandtstadter & Rothermund, 1994). However, flexibility and adaptation may be reduced at both the psychological and biological levels, contributing to increased disease risk.

The profile of biological stress responses changes with age. Older age is characterized by higher levels of circulating catecholamines but reduced responsiveness to sympathetic stimulation (Lakatta, 1993). Thus, heart rate responses to challenging tasks are reduced, while a decrease in the dilation of blood vessels supplying working muscle results in increased blood pressure responsivity. Animal studies suggest that the magnitude of acute responses in the HPA system is unchanged with age, but that cortisol elevations are more prolonged in older animals, suggesting disruption to regulatory feedback mechanisms (Seeman & Robbins, 1994). A limited amount of evidence suggests similar processes are at work in humans, although increased cortisol responses to challenging tasks with age have also been described (Gotthardt et al., 1995). The magnitude of ACTH and cortisol responses to a simulated real-life challenge (a driving test) were shown to be inversely associated with self-esteem in an elderly cohort, suggesting that maintenance of psychological well-being in old age may help reduce adverse psychophysiological response patterns (Seeman et al., 1995).

8.02.6.3 Gender

Many of the medical disorders discussed in other chapters of this volume have different rates of occurrence in men and women. There are also consistently higher reports of psychological distress on measures such as anxiety and depression among women than men, and these differences do not appear to be accounted for by disclosure or response biases (Mirowksy & Ross, 1995). The question therefore arises of whether psychophysiological processes contribute to differences in disease and distress between the sexes.

Faced with identical challenges, young men tend to show more sustained cortisol reactions than young women (Kirschbaum, Wust, & Hellhammer, 1992), together with higher epinephrine responses (Frankenhaeuser, Dunne, & Lundberg, 1976). Men also manifest greater blood pressure responses than women, and this pattern can be seen even in childhood (Allen, Stoney, Owens, & Matthews, 1993; Murphy, Stoney, Alpert, & Walker, 1995). By contrast, heart rate responses are typically greater in women. Studies comparing women at different phases of the menstrual cycle have not reached a consensus about effects on stress responsivity (Stoney, Owens, Matthews, Davis, & Caggiula, 1990). However, it is probable that the low responsivity of young women is mediated at least in part by circulating estrogen, and after menopause the blood pressure stress responsivity and ambulatory blood pressure of women approach that of men (Owens, Stoney, & Matthews, 1993).

8.02.6.4 Ethnicity

There are pronounced ethnic differences in the prevalence of a variety of diseases (Murray & Lopez, 1996). The contribution of psychosocial factors has been investigated extensively in relation to cardiovascular disorders and diabetes. Noninsulin dependent diabetes is particularly common among Micronesians, native Americans, Hispanic Americans, and in migrants from South Asia to the UK. It is accompanied by a high prevalence of insulin resistance, low concentrations of HDL-cholesterol and high levels of abdominal obesity. Although there have as yet been few studies of psychophysiological processes, it is plausible that these ethnic differences may relate to the stress-related pathways described in Section 8.02.3.3.1.

Hypertension is more prevalent among black than white people in urbanized societies, and research indicates that factors such as repressed hostility, socioeconomic status, and social integration may all contribute (Anderson, Myers, Pickering, & Jackson, 1989). There have been many studies of differences in the responses of black and white volunteers to laboratory mental stress tests. The data suggest that black people show greater increases in peripheral vascular resistance than whites, particularly when confronted by passive aversive tasks such as the cold pressor test (Saab et al., 1992). White people by contrast show increases in heart rate and myocardial contractility, indicative of greater sensitivity to beta-adrenergic sympathetic nervous stimulation. These findings indicate that when faced with the same psychosocial demands, ethnic differences in responsivity may contribute to differential disease risks.

8.02.6.5 Socioeconomic Status and Education

The major sources of morbidity and mortality in developed countries show strong socioeconomic gradients, with higher prevalence among people of lower socioeconomic status (Blane, Brunner, & Wilkinson, 1996; Kaplan & Keil, 1993). Socioeconomic status may be assessed by a variety of indices including occupation, income, type of housing and education. Differences are present not only in manifest disease but in subclinical pathology, and are present throughout the life course. As noted earlier, psychosocial demands are greater among people of the lower socioeconomic status, while perceived social support is poorer (Turner & Marino, 1994; Turner et al., 1995). Low socioeconomic status is associated with chronic stressors such as excessive work demands, inadequate rewards, economic hardship and uncertainty, increased exposure to crime and noise in everyday life, frustration in expectations associated with social roles, and greater barriers to achieving life goals (Aneshensel, 1992). A combination of biological factors, health behaviors and psychosocial influences such as poorer support appears to account for much of the socioeconomic gradient in mortality and cardiovascular disease risk factors (Lynch, Kaplan, Cohen, Tuomilehto, & Salonen, 1996). However, some social variations require further explanation. For example, Nordentoft et al. (1996) found that life stress and education were independent predictors of premature delivery in a large sample of pregnant women. There is limited evidence that psychophysiological responsivity is associated with socioeconomic markers such as education and work status, but further study of these issues is essential (Carroll, Smith, Sheffield, Shipley, & Marmot, 1997; Owens et al., 1993)

8.02.6.6 Genetic Factors

Genetic factors are probably responsible for many of the differences between people who are at risk of psychophysiological disease. They may operate in several different ways. First, twin adoption studies indicate that a substantial proportion of the variance in the experience of adult life events and in social support is accounted for by genetic influences (Bergeman, Plomin, Pedersen, McClearn, & Nesselroade, 1990; Plomin, Lichtenstein, Pedersen, McClearn, & Nesselroade, 1990). Psychological factors such as optimism, hostility, and Type A behavior are also heritable. Consequently, the likelihood that a person will manifest intense psychophysiological responses is determined not only by his or her experience, but by genetic makeup. Second, the magnitude of psychophysiological stress responses to standardized tasks in the laboratory shows significant heritability (Hewitt & Turner, 1995). Third, genetics contribute to other predisposing factors like obesity, and to activities such as alcohol consumption, thereby increasing risk of disease through behavioral pathways. Overall, there is a sizeable genetic contribution to risk of illnesses such as coronary heart disease, hypertension, rheumatoid arthritis, diabetes, and certain types of cancer, so it is likely that psychophysiological processes will have a greater impact on an individual who is genetically predisposed to a particular condition.

8.02.6.7 Individual Patterns of Psychophysiological Responses

The final predisposing factor that needs to be considered is each person's tendency to show a particular pattern of physiological responsivity to psychosocial demands. As noted earlier, physiological responsivity is a relatively stable characteristic for each individual, and it is one that emerges early in life in animals and humans (Brown-Borg, Klemcke, & Blecha, 1993). Lewis, Thomas, and Worobey (1990) showed that infants who were emotionally reactive to a painful stimulus (inoculation) at two months old were more prone to infection over the subsequent year, probably because of a tendency towards stress-induced immunosuppression. In adult life, many people show individual-response specificity, which is the tendency to respond maximally and consistently in a particularly physiological pathway. It has typically been evaluated by measuring a range of autonomic responses to a series of different tasks. A person manifests individual-response specificity if they are maximally reactive in one measure across situations. Individuals differ in the measures in which they are most responsive, so some may be blood pressure responders, while others are most sensitive in terms of the electrodermal system or cortisol (Steptoe, 1984a). Multivariate analyses suggest that about one-third of people show consistent individual-response specificity. It is appealing to speculate that these people may be prone to developing disorders associated with the psychophysiological parameter in which they are most responsive.

8.02.7 PSYCHOPHYSIOLOGICAL MODELS OF DISEASE

The previous sections have described the physiological responses that are activated when psychosocial demands outweigh the resources available to the individual, and have outlined the factors that increase vulnerability and predisposition to disease. There remain the actual mechanisms through which disease is initiated and exacerbated. However, before these psychophysiological processes are described, it must be emphasized that they are not the only pathways through which psychosocial factors affect disease and physical health. Psychosocial factors may influence disease not only through psychophysiological processes, but also through behavioral, affective, and social-cognitive pathways. These latter will not be discussed here, since they have been extensively described previously (Cohen & Rodriguez, 1995; Steptoe, 1991).

Cognitive processes such as the identification of symptoms or decisions to seek help from health professionals, and behaviors such as alcohol consumption, adherence to medical advice, and risky sexual practices, may all be affected by the psychosocial factors described in this chapter. They may in turn impact on diagnosis and disease. It is frequently difficult fully to apportion accountability to psychophysiological and behavioral mediators. For example, both poor social support and depressed mood have been shown to predict early mortality following myocardial infarction (Berkman, Leo-Summers, & Horwitz, 1992; Frasure-Smith et al., 1993). The known effects of these factors on physiological systems relevant to coronary disease may be responsible, but so might behavioral factors. For instance, there may be differences in adherence to medication, or small variations in the speed with which help is sought following the onset of symptoms, that might occur between the socially isolated or depressed patients and others. These might determine whether or not the patient survives a fresh cardiac event irrespective of psychophysiological disturbances.

Notwithstanding these considerations, there is ample evidence for psychophysiological involvement in disease pathology. In fact, several types of mechanism have now been identified, and these are summarized below. It is important to recognize the differences between them, since the role played by psychophysiological factors in disease pathology is somewhat varied. Moreover, the types of research design needed to evaluate the various mechanisms are also quite distinct.

(i) Psychosocially induced physiological reactivity as a causal factor.

(ii) Psychosocially induced physiological reactivity as an inhibitor of host resistance and host defenses.

(iii) Psychosocially induced physiological reactivity as a disruptive factor on existing pathology.

(iv) Psychosocially induced physiological reactivity as a trigger of acute clinical events.

8.02.7.1 Physiological Reactivity as a Causal Factor

The first possibility is that psychophysiological reactivity is directly responsible for disease. Particular individuals show heightened reactivity in specific physiological parameters such as blood pressure, gastrointestinal motility, or muscle tension in the head and neck. Through regular or sustained exposure to psychosocial demands that over-tax resources, these physiological responses may be repeatedly elicited and in due course may gravitate from acute reactions to sustained pathology. Of course, physiological reactivity does not act alone, but against the substrate of predispositions outlined in Section 8.02.6.

The type of study needed to evaluate this mechanism is a longitudinal investigation in which psychobiological predispositions and reactivity patterns are measured at the outset, and exposure to the stressors that trigger appropriate physiological responses is tracked. It would then be predicted that people with heightened reactivity in a particular physiological response system, and who also experience psychosocial demands that elicit these reactions over a sustained period, will be at increased risk for developing the disease.

This type of study is difficult to carry out in humans, although it forms the basis of some animal models of pathology (Manuck et al., 1989). More readily available in humans is evidence that people with a variety of disorders tend to react to cognitive and emotional challenges with heightened responses in the physiological systems relevant to their disorder. Thus people with hypertension typically show larger blood pressure responses to mental stress tests than do those with normal blood pressure. Asthmatics react to challenges with greater increases in bronchoconstriction, people with irritable bowel or irritable colon show greater disturbances in motility of the gut, patients suffering from tension headache or chronic low back pain show heightened reactivity in muscles in appropriate tissues, and so on (Flor & Turk, 1989; Kumar & Wingate, 1985; Steptoe, 1997).

These studies are consistent with psychophysiological reactivity being involved in disease etiology, but do not provide strong evidence. The reason is that disturbances in reactivity to behavioral challenges may be secondary to the pathological changes characteristic of the disease itself. Thus bronchial hyper-reactivity is a general process in asthma that triggers reactions to exercise, cold, housedust mite and other factors apart from emotional challenges. In other conditions as well, exaggerated reactivity may be an effect rather than cause of the medical condition.

A way of circumventing this cause–effect problem is to identify people who are at enhanced risk for a particular disorder prior to the onset of pathology. If aberrant reactivity is present among these individuals, then the psychophysiological disturbance clearly precedes the development of the disorder. Unfortunately, markers of enhanced risk are rare for many medical disorders, making this approach difficult to implement. The field in which this strategy has been developed most vigorously is hypertension, since there is a moderate but consistent hereditary contribution to blood pressure level. This means that young people whose parents have hypertension are at increased risk themselves. The blood pressure and other cardiovascular responses to mental stress of normotensive people with and without a family history of hypertension have therefore been examined. It is frustrating that despite a large number of studies, findings have been inconclusive, with heightened reactivity being recorded from high risk people in some studies but not in others (Steptoe, 1997). The explanation for the variability in results is not clear, although the nature of psychological demands and the co-existence of vulnerability factors such as emotional inhibition may be relevant. Perhaps more importantly, even this research strategy does not completely overcome the cause–effect problem in interpretation. A variety of pathophysiological processes are disturbed in young normotensives with a family history of hypertension, including sodium transport, vascular distensibility and left ventricular structure. Consequently, the possibility cannot be ruled out that heightened psychophysiological reactivity is secondary in these groups, just as it may be in established hypertensives.

Longitudinal studies have also been conducted, testing the hypothesis that normotensive people with heightened reactivity will be at increased risk of developing hypertension in the future. Here the evidence is rather more compelling, with an increasing number of studies showing that high reactivity does predict future hypertension (Light, Dolan, Davis, & Sherwood, 1992; Treiber et al., 1996). Blood pressure reactivity to mental stress is also associated with the pathological consequences of hypertension such as hypertrophy of the left cardiac ventricle (Hinderliter, Light, Girdler, Willis, & Sherwood, 1996). Yet it is also the case that some longitudinal studies have failed to show any prediction of future cardiovascular problems (Carroll et al., 1995). Two issues are relevant. The first is that heightened psychophysiological reactivity may only be significant in the presence of co-factors such as obesity or salt sensitivity. Second, it is necessary in longitudinal studies to include measures of the life experience of the cohort over the follow-up period. Unless this is done, one important element of the psychophysiological causal hypothesis is missing.

8.02.7.2 Physiological Reactivity as an Inhibitor of Host Resistance and Defense

The second mechanism through which psychosocially-induced physiological reactions may influence disease is by altering physical vulnerability in ways that render the person more susceptible to invasive organisms. The mechanism is presented diagrammatically in Figure 2, which shows four possible scenarios linking exposure to pathogens and bodily defenses. The mechanism is illustrated through the case of infectious agents and immune defense, although it is equally applicable to other pathogens and defense systems. Panel A represents the situation when the organism mounts an adequate immune response that tackles the infection effectively and prevents disease. In panel B, exposure takes place in the presence of a stress-induced impairment of immune response, allowing the infection to be acquired and illness to develop. This is the situation that pertains when physiological reactivity alters host resistance.

This psychophysiological mechanism is different from the process described in Section 8.02.7.1 in two important ways. First, the psychophysiological response is not presumed to cause illness, but rather to influence vulnerability. Second, it is not necessary to postulate that people are exposed to intense, repeated stressors in order for disease risk to be enhanced. Rather, heightened vulnerability for a single short time period may be sufficient, if it is contiguous with a critical state of invasion.

The ideal type of study of this mechanism is a longitudinal investigation in which psychosocial factors are monitored together with measures of bodily defenses, exposure to infectious agents, and illness. Such studies are difficult to carry out at a technical level and also require high levels of cooperation from participants. Interpretation of results is also complicated by the two additional scenarios shown in panels C and D of Figure 2. Panel C describes a situation when the infectious agent to which the individual is exposed is particularly virulent. Under these circumstances, illness may occur even though immune responses are intact. Another possibility is that bodily defenses are disrupted, but since there is no simultaneous exposure to a pathogen, no illness results (Panel D). Taking account of all these alternatives probably goes beyond the scope of any study in humans that has been conducted thus far.

Some of the most convincing evidence for psychosocially induced impairment of host defenses comes from studies in which infectious agents were administered experimentally. Cohen, Tyrrell, and Smith (1991) demonstrated that the acquisition of infection following administration of known doses of common cold viruses was related to a composite measure of psychological stress; subsequent analyses suggested that infection rate was predicted by negative affect and subjectively-rated stress, while illness was predicted by negative life events. These findings have been replicated in broad outline, albeit without assessment of the immune parameters that might have mediated clinical effects (Cohen, Boyle et al., 1995, Stone et al., 1992).

Psychosocial factors are associated with infectious illness in naturalistic settings as well (Cohen & Williamson, 1991). For example, the herpes virus responsible for cold sores and genital lesions may remain latent in the body after the first exposure, but can be reactivated to produce new episodes of illness. Several retrospective studies have shown that recurrence is more likely during episodes of psychosocial stress. One prospective investigation with daily ratings of mood indicated that the ten days prior to a recurrence of genital herpes were characterized by elevations in ratings of nervousness (Dalkvist, Wuahlin, Bartsch, & Forsbeck, 1995). Interestingly, Turner-Cobb and Steptoe (1996) found in another longitudinal experiment that symptoms of upper respiratory tract illness were preceded by high levels of perceived stress for two to three weeks. In the study of immune function in care-givers for dementing patients alluded to in Section 8.02.3.4.3, Kiecolt-Glaser et al., 1991) reported that care-givers experienced longer episodes of illness over a 12-month follow-up than did controls. This suggests that the immune suppression recorded among care-givers may have led to prolongation of illness.

Evidence for psychosocially-induced impairment of host resistance having a clinical role is therefore becoming increasingly convincing. In studies of pathophysiology, there is a new understanding that infectious processes are not confined to traditional self-limiting disorders, but may contribute to conditions such as peptic ulcer, gastric cancer, dementia, vasculitis, and insulin-dependent diabetes (Lorber, 1996; O'Connor, Buckley, & O'Morain, 1996). As these mechanisms are uncovered, the role of psychophysiological processes in reducing resistance may assume even greater importance.

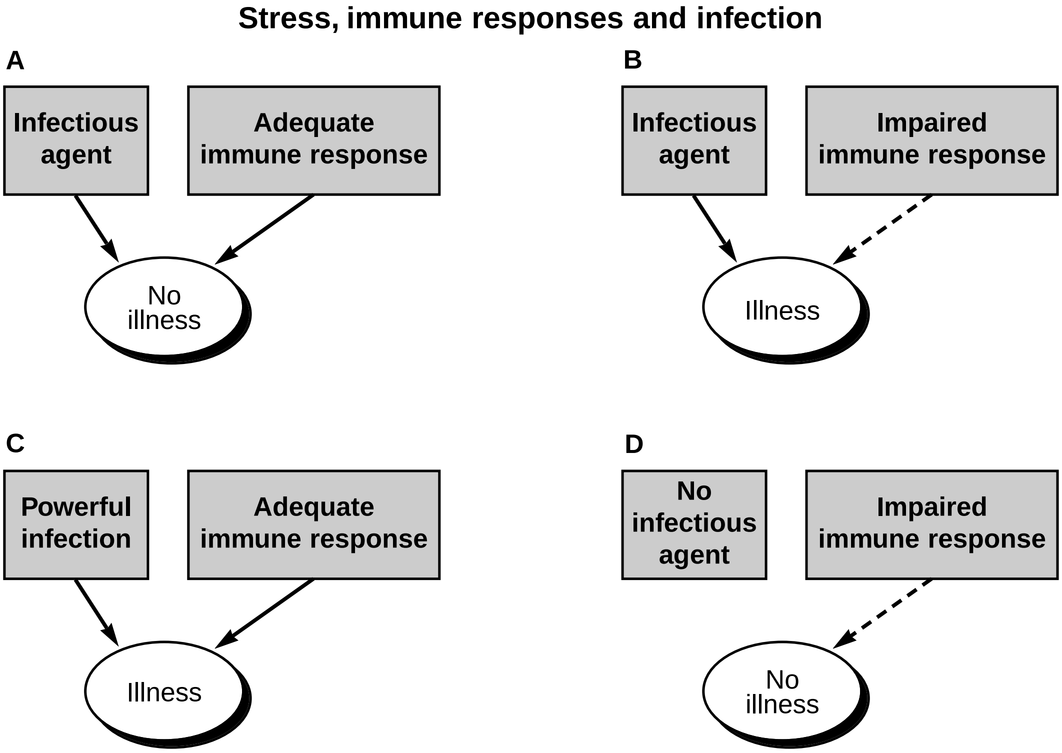

Figure 2 Schematic outline of associations between immune defenses and infection.

8.02.7.3 Physiological Reactivity as a Disruptive Factor

If psychosocially induced physiological reactions do not act as causal factors, how do they contribute to the disease process? An important possibility is that psychophysiological reactions act on existing pathology to disrupt regulatory mechanisms. The result may be exacerbation of the patient's clinical state, possibly leading to symptomatic episodes, or to more rapid degeneration in progressive conditions than would otherwise be the case.

The role of physiological reactivity as a disruptive factor differs from its involvement in the processes outlined in Section 8.02.7.1 and 8.02.7.2 in several ways. First, this mechanism is operative in people already suffering from disease, although the pathology may not necessarily have reached the stage of clinical diagnosis. It is particularly likely to be active in chronic or episodic conditions such as pain syndromes, bronchial asthma, and diabetes. Second, the influence of psychophysiological responses may be manifest at the level of day-to-day clinical status, and consequently relatively minor daily hassles may be influential. Third, the physiological reactions may either be directly involved in pathology (such as disturbances of bronchoconstriction in asthma) or may disrupt host resistance, as in the case of autoimmune conditions. There may be some problems such as insulin-dependent diabetes where effects could be mediated either directly through disturbances of insulin metabolism or indirectly through failures in resistance to enteroviruses.

There is a substantial amount of data showing that symptoms and other indicators of medical conditions covary with psychosocial factors, and the mechanism outlined here may be responsible for these associations. By way of illustration, factors such as negative mood and daily stressors have been shown to covary with disability and symptoms in rheumatoid arthritis (Affleck, Tennen, Urrows, & Higgins, 1994), irritable bowel syndrome (Suls, Wan, & Blanchard, 1994), the chronic inflammatory condition systemic lupus erythematosus (Adams, Dammers, Saia, Brantley, & Gaydos, 1994), headache, Crohn's disease (Brantley & Jones, 1993), insulin-dependent diabetes (Goldston, Kovacs, Obrosky, & Iyengar, 1995), and phantom limb pain (Arena, Sherman, Bruno, & Smith, 1990). However, the problem arises of whether these associations reflect genuine influences on pathology, or effects on symptom reporting and complaints. In order to show that psychophysiological processes are operative at the biological level, it is necessary to measure covariation of psychosocial factors with physiological regulatory parameters as well as symptoms. Here findings are more sparse, but nevertheless suggestive. Thus several studies of insulin-dependent diabetes have shown that stressors influence blood glucose levels and metabolic control independently of variations in diet, exercise, or compliance with medical advice (Goldston et al., 1995; Halford, Cuddihy, & Mortimer, 1990). In patients with rheumatoid arthritis, the experience of minor life events was associated with fluctuations in T and B lymphocyte counts (Zautra et al., 1989). As methods of physiological monitoring become more sophisticated and less obtrusive, it is likely that more influences of this kind will become apparent.

The role of psychosocial factors in the development of cancer and progression of HIV infection are controversial issues that are discussed in other chapters of this volume. It is probable that if psychophysiological processes are involved, they act through the dysregulation of immune surveillance in a fashion similar to the mechanisms outlined in this section.

8.02.7.4 Physiological Reactivity as a Trigger of Acute Clinical Events

The fourth distinct psychophysiological mechanism in disease concerns the elicitation of acute clinical events. It is possible that psychophysiological responses can be so intense as to trigger episodes of serious illness, and possibly even death. Such an effect is unlikely in the absence of severe underlying disease rendering the victim especially vulnerable. The mechanism is distinctive in that a single occurrence may have serious clinical consequences.

It has been proposed that such a process may be involved in the precipitation of epileptic seizures (Webster & Mawer, 1989). One study of civilians under threat of missile attack showed seizures to be triggered by raid alarms in a small group of patients (Neufeld, Sadeh, Cohn, & Korczyn, 1994). It is conceivable that the process is also relevant to the occurrence of stroke, although evidence is sparse (House, Dennis, Mogridge, Hawton, & Warlow, 1990). Probably the best illustration of the impact of psychophysiological processes on acute clinical events is in the cardiovascular field, with the triggering of myocardial infarction and sudden cardiac death. Recent studies of myocardial infarction victims suggest that the disturbances of cardiac rhythm and coronary blood flow described in Section 8.02.3.2.2 may precipitate clinical events in susceptible individuals. One study assessed anger during the hours prior to acute infarction in comparison with other time periods (Mittleman et al., 1995). A high incidence of severe anger was recorded in the two hours before symptom onset. The effect was not present among patients taking beta-blockers, suggesting that stimulation of coronary vasospasm or thrombotic processes by sympathoadrenal activation may have been involved. Emotional triggers of acute cardiac events have been reported in other studies as well (Tofler et al., 1990). Jain, Burg, Soufer, & Zaret (1995) showed that cardiac patients who responded to laboratory mental stress with disturbances of myocardial function were more likely over the next two years to have acute infarctions or develop unstable angina pectoris than were nonresponders to stress. Taken together, these findings suggest a plausible link between psychosocially-induced physiological reactions and acute episodes of clinical disease.

8.02.8 CONCLUSION

The psychophysiology of disease is a vigorous and exciting area of research. It involves the integration of several disciplines including neuroscience, pathophysiology, and health psychology, and in each of these areas new discoveries are constantly changing our levels of understanding. The complexity of links between the brain, peripheral physiological function, and disease risk is formidable, and linear models are of limited value. The broad processes linking psychophysiological factors with disease risk are now understood, although many of the biological mediators remain tantalizingly illusive. Important challenges for future research include delineation of the processes through which psychosocial factors such as social inequality and social isolation affect disease, understanding how emotional and behavioral coping responses can modify physiological reaction patterns and contribute to resistance and vulnerability, and defining the ways in which psychophysiological knowledge can be harnessed for prevention and disease management. Psychophysiology is one of the cornerstones of clinical health psychology, and is of prime importance in understanding how psychological and social experience can influence health and disease.

8.03.1 INTRODUCTION

This chapter is concerned with a range of psychological processes involved in the entry into, experience of, and outcome from health care. It begins by considering how people make sense of and respond to symptoms, leading up to the decision to seek health care. Following this, a large part of the chapter is concerned with the process and outcome from medical consultations. Finally, it considers some very specific health-care settings such as hospital environments and surgical treatments where psychological factors can play an important role in adaptation and recovery.

Thus, the chapter covers the three following broad areas, which form its major subsections: (i) perceiving symptoms and entry into health care, (ii) health-care professional—patient communication, and (iii) health care in hospital.

It is important to note at the outset that this chapter does not deal with the nature of health-care systems and the ways in which these are organized and accessed. Health-care systems vary greatly from country to country and there can be considerable differences in the ease of access to health care, the relative roles of the primary and secondary care sectors, and the ways in which health care is funded and delivered. All these are extremely important contextual factors which can directly influence the experience of health care for the individual but a consideration of their influence is beyond the scope of this chapter. The focus here will be on those psychological processes involved in the entry into and use of health services, and which may be seen across different health-care systems.

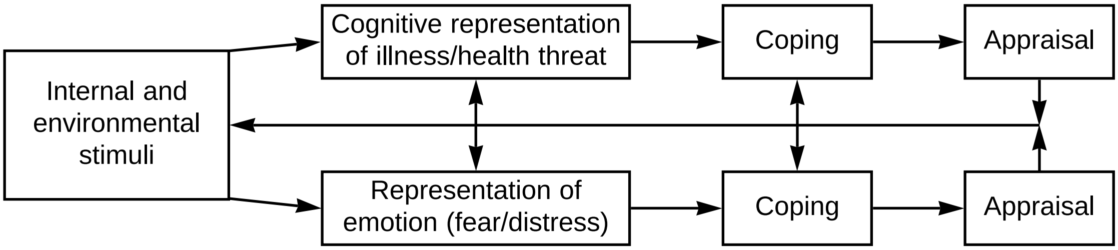
8.03.2 THEORETICAL BACKGROUND

Although this chapter focuses on a range of psychological processes and issues, there is a general model which unifies many of the various themes, particularly from the patient's perspective. This is the self-regulatory approach (e.g., Carver & Scheier, 1990; Leventhal et al., 1997). The core concept here is that the individual attempts to make sense of threats to health using preexisting knowledge or schema which give rise to behavioral responses (e.g., taking nonprescribed medicines, deciding to seek medical help, following medical advice, etc.). Thus, many of the individual's behaviors within the health-care setting can be understood from the perspective of their own thoughts and ideas. These are not static but may well change and develop with the experience of new symptoms or information. Self-regulation is therefore a dynamic process in which the individual attempts to preserve the sense of self and to solve the problem of what is happening to their health.

The individual's initial representations of a health problem (e.g., "this stomach pain is a temporary problem brought on by something specific such as over-eating") give rise to specific coping procedures (e.g., not eating, taking antiacids) which are appraised for their effectiveness (see Figure 1). If the appraisal process results in the view that the mode of coping is not working, then another coping procedure may be selected or the individual may change their view about the nature of the problem (e.g., "this stomach pain has lasted for the whole day and has not responded to indigestion medication—it must be something more serious") and their response to it.

The core of the self-regulatory approach is the individual's own understanding or representation of their situation. Work by Leventhal and colleagues (Leventhal et al., 1997; Leventhal, Nerenz, & Steele, 1984) has shown that this representation is built around five distinct but interrelated themes, namely identity, cause, time-line, consequences, and cure/control. On experiencing a new symptom, the individual typically will provide a label or description and possibly search for or link this with other symptoms which they are experiencing. These aspects constitute their perceived identity of the problem, and typically this is linked with a causal explanation, as well as some expectations about how the problem will last (time-line), its likely effects (consequences) and the extent to which it is amenable to cure or control. These representations will influence how the individual responds to the problem in the short-term and the longer-term, if it persists. They will also provide the conceptual framework for providing and making sense of information within consultations with health-care professionals, as well as for evaluating the appropriateness and efficacy of recommended treatment or advice.

In some of the following sections (e.g., symptom perception), this self-regulatory, schema-based approach will be very obvious but in others it will be less clear or less pertinent.



Internal and environmental stimuli
Cognitive representation of illness/health threat
Coping
Appraisal
Representation of emotion (fear/distress)
Coping
Appraisal

Figure 1 Leventhal's self-regulatory model (adapted from Leventhal, Diefenbach, & Leventhal, 1992).

Nevertheless, it is a central tenet in this chapter, just as it is in many other areas of psychological research. Just as individuals actively interpret and make sense of their physical (Eysenck & Keane, 1995) and their social environment (Fiske & Taylor, 1991), it will be shown that the psychological processes involved in experiencing symptoms and utilizing health care can be understood in a similar way (Weinman & Petrie, 1997).

8.03.3 PERCEIVING SYMPTOMS AND ENTRY INTO THE HEALTH-CARE SYSTEM

There are many reasons why people gain access to health care. Increasingly people are encouraged to attend on a regular basis for check-ups or for screening or preventive purposes, but by far the most common reason for seeking medical help is the experience of a symptom. At first sight, the relation between symptoms and entry into health care might appear straightforward. A simplistic model of the relation between symptom experience and health-care utilisation would probably involve the idea of a threshold of symptom severity, and that individuals would only seek care when this notional threshold is exceeded. As we shall see, this simple model is untenable and it is necessary to understand first how symptoms are perceived and then to examine how they influence behavior, including help-seeking behavior.

8.03.3.1 The Nature and Experience of Symptoms

There are continuous changes in bodily functions but individuals have limited awareness of these. In a series of studies, Pennebaker (1982) examined the awareness of a number of changing bodily processes (e.g., heart rate, finger temperature) and showed that this process is neither direct nor accurate The awareness and interpretation of bodily processes has been found to involve a range of factors, as will be outlined below, and an understanding of these is a basic first step in explaining why people seek help for health problems. A fundamental issue here concerns the point at which the individual decides that a particular change in bodily functioning might constitute a symptom and may therefore be indicative of a medical condition. Symptoms are experienced quite frequently. This has been found by asking people to recall symptoms experienced in the preceding days or weeks or by getting them to record their symptoms, by keeping a health or symptom diary. Typically people recall experiencing between two and three symptoms per week and very often symptom diaries reveal the presence of daily symptoms. Most of these are transient and, while they may make the individual wonder about their nature and cause, they may not give rise to any further behavior such as taking medication or seeking medical help. One study, of people keeping health diaries, found that while symptoms were recorded on 38% of the days in the study period, medical care was sought for only 5% of those symptoms (Verbrugge, 1985). This "clinical iceberg" has been reported elsewhere (e.g., Last, 1963) and it is clear that neither the experience nor the severity of a symptom provides an adequate explanation of why people seek medical help. There are many people who seek help for symptoms which doctors consider to be "minor" or "trivial" and there are also people who delay or do not seek help for symptoms which may reflect serious or life-threatening conditions, and some examples of this will be discussed in Section 8.03.3.4. In order to understand the relation between symptoms and help-seeking behavior, it is necessary first to examine how symptoms are perceived and then to examine their role, alongside other factors, in initiating access to health care.

The studies of Pennebaker (1982) and others show clearly that symptom perception shares many characteristics of other perceptual processes, such as those which are involved in the recognition of objects and sounds in the external world. Thus, there is considerable evidence that bodily changes are not perceived accurately and that there can be large variations in what is attended to and how it is perceived and interpreted. Just as attentional processes and "top-down" influences in the form of knowledge and prior experience can determine how objects are perceived (Eysenck & Keane, 1995), the same factors play a critical role in influencing our awareness of and interpretation of bodily changes.

Physical symptoms are often ambiguous and their interpretation involves a number of cognitive-perceptual processes which are subject to both psychological and social influences (Cioffi, 1991; Pennebaker, 1982). The experience of a bodily symptom initiates an active memory search in order to generate comparisons between current stimulus and the concrete and abstract knowledge contained in the person's illness schemas. These cognitive structures are the dominant source of information for the appraisal of health threats (Leventhal et al., 1997). According to Bishop (1991), the information contained in illness schemas forms a stable knowledge base or prototype which acts as a standard for the comparison and interpretation of bodily symptoms. Current symptoms are compared with prototypical patterns of illness retrieved from long-term memory. If there is a close enough resemblance between the illness prototype and the current symptoms, then a congruent interpretation will be made. However, H. Leventhal and Diefenbach (1991) propose that comparisons are made not with illness prototypes but with specific illness episodes. They suggest that matching to prototypes is likely to result in an ambiguous outcome and that the resulting uncertainty will initiate additional, more specific searches. Croyle and Barger (1993) comment that both types of matching may occur. Frequently experienced illnesses such as flu may promote the formation of prototypes, whereas unusual symptom clusters may give rise to matching with specific illness episodes. Cioffi (1991) has described a model of symptom interpretation which is compatible with the self-regulation model. Her model proposes that symptom interpretation is a function of interactions between "bottom-up," stimulus-driven processes, situational cues, and "top-down" processes which reflect the influence of higher level cognitive structures (e.g., knowledge, expectations) on other cognitive functions such as attention and memory. According to Cioffi (1991), ambiguous physiological changes compete with other events for a share of our fixed attentional capacity. If the stimuli are strong enough, or if there is little competition from other sources, the sensations are noticed and given a somatic label. An attribution is then made regarding the cause of the change and its consequences. Causal attributions reflect the relative influence of the procedures involved in the interpretative process and may be symptomological (e.g., muscle pain as a symptom of illness), or nonsymptomological (e.g., muscle pain due to exercise). Symptomological attributions can reflect preexisting hypotheses such as particular health concerns which may bias both attention to bodily stimuli and choice of attribution. Alternatively, in the absence of a prior hypothesis, a memory search is launched in order to generate plausible attributions. These processes, along with subsequent behavioral responses, are mediated by factors such as mood, coping repertoire, available choices, and both situation-specific and general goals. A schematic of this model is shown in Figure 2.

8.03.3.2 Factors Influencing Symptom Perception

The appraisal of health threats may be influenced by a range of personal, psychological, social, and cultural factors (Croyle, 1992). While many of these factors interact, they can be loosely categorized into those which affect or are a part of the self-system and those which stem from external, social, and cultural influences.

8.03.3.2.1 Attentional focus

Symptom perception is subject to the same limits and biases as other types of sensory processing, where there are well-demonstrated limits in attentional capacity which can be influenced by internal states, perceiver's intentions, and environmental stimuli and contexts (e.g., Kinchla, 1992). Similarly, a number of studies have shown that symptom perception depends on what the individual is attending to as well as what is happening in the perceiver's environment. For example, Pennebaker (1982) reports a study in which the symptom reports of fatigue were compared in two groups of joggers, one running around a track and the other on a cross-country run. The cross-country group report less fatigue, presumably because of the more varied and interesting surroundings. Similarly it has been reported that, while watching films, people are more likely to notice itchy/tickly throat sensations and then cough during boring parts of the film.

Attention to symptoms is to some extent under strategic control and a number of studies have examined the effects of attention to or distraction from physical sensations (Cioffi, 1991). Experimental studies examining the effects of various unpleasant stimuli (e.g., loud noise, pain induced by immersing one's hand into iced water) on tolerance and arousal, have shown that active distraction can have short-term advantages over more direct attention to the stimuli (Mullen & Suls, 1982). However, focused attention results in more favorable outcomes than distraction when the noxious stimulus is chronic and when the attentional strategy involves focusing on concrete aspects of the sensation (Suls & Fletcher, 1985). This raises the question as to whether focusing on aversive symptoms such as pain could have any positive or negative effects which could be utilized in the clinical situation. Work by Leventhal, Leventhal, Shacham, and Easterling (1989) indicates that focusing on sensory properties of sensations can result in reduced levels of distress. This type of sensory focusing or monitoring serves to direct attention to more objective, sensory properties of the stimulus and away from the more negative, emotionally arousing aspects, resulting in a more neutral interpretation and response. This can be used to good effect in providing sensory information to patients prior to stressful medical procedures and surgery (see Section 8.03.5.5).

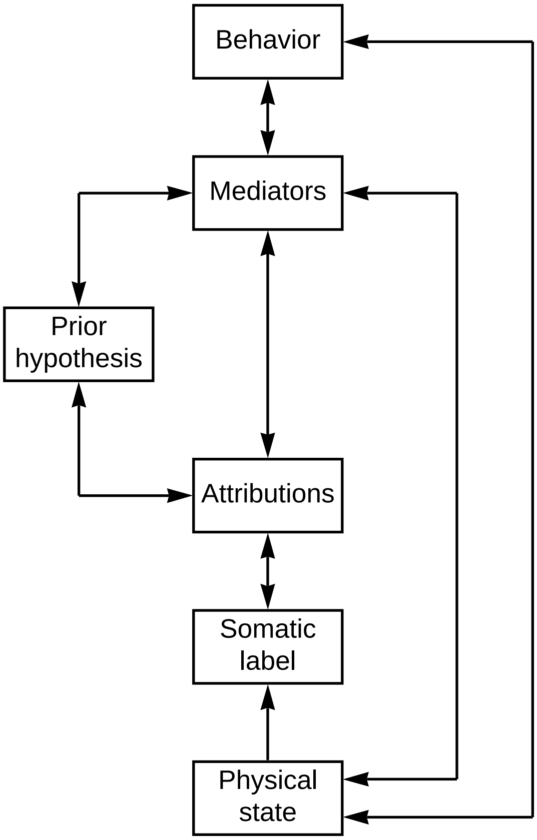


Figure 2 A model of symptom perception (adapted from Cioffi, 1991).

8.03.3.2.2 Knowledge and expectations

The knowledge contained within illness schemas imposes meaning on internal and external events (Leventhal et al., 1984). A powerful illustration of the influence of schema contents on the interpretation of somatic stimuli comes from studies of patients suffering from panic disorder and hypochondriasis whose catastrophic illness-related interpretations of benign bodily stimuli reflects their current health concerns (Warwick & Salkovskis, 1990). Similar influences of catastrophic interpretations on symptoms can be seen in patients with chronic fatigue syndrome (Moss-Morris, 1997) and with chronic pain disorders (e.g., Keefe, Brown, Wallston, & Caldwell, 1989). In all these situations the catastrophizing individual will be likely to interpret a bodily symptom in a very negative way (i.e., perceive it as indicative of a serious problem), which then will generate even higher levels of anxiety and an increased focus on and negative interpretation of related symptoms.

In addition to personal illness experience, illness schemas are derived from illness information current in the culture and from social communication with other people, particularly medical practitioners (Leventhal et al., 1984). The body or self schema also affects the interpretation of health threats as it provides a basis for comparing deviations from the norm and for discriminating normal age-related changes from illness (Keller, Leventhal, Prohasha, & Leventhal, 1989). Indeed, with older people there is evidence of a bias towards age-related attributions (i.e., "it's because I am old") which can serve to delay seeking help or prevent taking appropriate action (E. Leventhal & Crouch, 1997).

8.03.3.2.3 Disposition and emotions

The content and activation of illness schemas may also be influenced by dispositional factors such as psychological traits and emotions (H. Leventhal & Diefenbach, 1991; Leventhal, Diefenbach, & Leventhal, 1992). For example, Leventhal et al. (1992) propose that personality factors such as repression-sensitisation (Byrne, 1964) may affect illness representations by influencing attention to and interpretation of somatic states. Also, high levels of negative affectivity, which is highly correlated with neuroticism (Watson & Clark, 1984), have been found to predict symptom reporting and health complaints, but not actual health status (Watson & Pennebaker, 1989). Laboratory studies involving experimental induction of a negative mood state in volunteer subjects results in more negative judgements of health status and higher levels of symptom reporting than is reported by comparison subjects who had undergone positive mood induction (Croyle & Uretsky, 1987). Similarly, when individuals are asked to keep a diary of symptoms and moods, they report higher levels of symptoms during negative mood states (Verbrugge, 1985).

8.03.3.2.4 Contextual factors

Social information and the environmental and cultural context also affect symptom perception (Croyle & Barger, 1991). When intrapersonal memory searches aimed at establishing the meaning of symptoms fail to provide an answer, social information becomes an important factor. In particular, the social comparison process, in which illness information is shared within the social network, has a significant influence on symptom appraisal (Leventhal & Diefenbach, 1991). Medical sociologists describe the way people use "lay referral" networks in trying to make sense their symptoms. These reflect the use of advice given by family and friends, who may often refer the individual to others who are known to have knowledge or experience which could help in throwing some light on the nature of the problem (see Armstrong, 1989).

Situational and contextual cues can play an important role in interpreting symptoms and in the generation of illness representations. For example, Baumann, Cameron, Zimmermann, and Leventhal (1989) found that, in the presence of a stressful life event, participants were more likely to interpret ambiguous symptoms as signs of stress than signs of illness. However, in the absence of stress, an illness interpretation was more likely. While external factors affected judgements about ambiguous symptoms, the effect was constrained by prior knowledge since context did not influence judgements about symptoms representing familiar illnesses.

8.03.3.3 Summary: Symptom Perception

The interpretation and response to symptoms is guided by illness schemas and involves several cognitive procedures. Typically, it begins with a search of long-term memory for comparable illness episodes, which promotes comparisons between the current state and previous experience. The outcome of the comparison process influences judgements about illness status and the identity of symptom clusters. These judgements can be mediated by the self-system and by external factors. The influence of the self-system reflects personal illness experience, the cultural knowledge base, the body schema, and personality traits. Symptom appraisal may also be biased by motivational processes aimed at minimizing health threats (Croyle, Sun, & Hart, 1997). For example, in an experimental study, Croyle, Sun, and Louie (1993) found that students who had been told that they had a potentially risky cholesterol level actually rated high cholesterol as less serious than those who were informed that theirs was in the normal range. Contextual and situational cues may also modify symptom interpretation, by the provision of specific local information (e.g., other people with similar symptoms) or via selective attention to specific aspects of the symptom experience (Cioffi, 1991).

8.03.3.4 Symptom Perception and Help Seeking

From a population perspective, the experience of symptoms is widespread and it is clear that the majority of these are transient and benign. For the individual, each symptom is evaluated in terms of its potential threat and decisions will be made on how best to respond on the basis of past experience and the present context. Thus, the perceived identity and cause of the symptom and its anticipated timeline and consequences will give rise to particular health-related behaviors. The most common initial response is to anticipate that the symptoms will be short-lived and can be attributed to a specific situational factor but there are important individual and cultural differences in this respect (Robbins & Kirmayer, 1991; Kirmayer, Young, & Robbins, 1994). These authors have carried out studies in which they presented various imaginary symptoms (e.g., dry mouth) to participants and asked them to choose the most likely cause from three alternatives, of which one was situational ("I need to drink more liquids"), one of which was physical ("there is something wrong with my salivary glands"), and the other was psychological ("I must be scared or anxious about something"). Situational explanations were chosen most frequently but some individuals showed clear biases towards selecting more physical or psychological explanations.

A bias towards opting for physical explanations for symptoms could lead to potential conflicts in health care, when tests fail to reveal any organic cause for a problem. To some extent this can be observed in people with chronic fatigue syndrome since they commonly attribute their symptoms to a physical cause in the absence of any confirmatory evidence (Moss-Morris, 1997). This, in turn, may reduce the perceived relevance of any psychological treatments which may be offered and have adverse effects on treatment adherence (see Section 8.03.4.3.3).

Seeking medical help is a relatively uncommon response since the majority of individuals wait, do nothing, or self-medicate (Freer, 1980). However, there has been considerable interest in understanding the responses of two groups of individuals: those who persistently seek help for what appear to be quite minor symptoms and those who delay seeking help while experiencing serious or life-threatening symptoms. Studies of frequently attending patients reveal that they are typically high in trait anxiety (Banks, Beresford, Morrell, Waller, & Watkins, 1975). This is consistent with the finding that trait anxiety is associated with a stronger attentional focus on internal bodily states, as well as higher levels of symptom reporting (Watson & Pennebaker, 1989). Also, these individuals are more likely to make more negative interpretations and attributions for particular symptoms than their less anxious counterparts (Sensky, Macleod, & Rigby, 1996). Given the negative cognitions which accompany anxiety (Lucock, Morley, Peaks, & White, in press), it is therefore not surprising that there will be greater concern and an accompanying need for reassurance but, as is discussed more fully at the end of this section, the rather minimal reassurance which is very often provided by the doctor is not likely to be effective in reducing anxiety or preventing further help-seeking.

Delay in seeking help for serious symptoms is a complex process which depends critically on the individual's perception of their symptoms as well as contextual factors, such as barriers to health care. Three stages of delay can be identified and have been described by Safer, Tharps, Jackson, and Leventhal (1979) as appraisal delay, illness delay, and utilisation delay. Appraisal delay involves the decision as to whether one is ill, given the particular pattern of symptoms which are being experienced. This stage is very much a function of the sensory properties of the symptoms as well as the way in which these are interpreted either from past experience, from reading about one's symptoms, or from discussion with others. The appraisal stage can be understood easily in terms of the models of Leventhal et al. (1997) and Cioffi (1991) which were outlined earlier in the chapter, since symptoms which do not activate threat-related illness schema are not interpreted as serious or potentially serious and are very unlikely to instigate help-seeking. Illness delay describes the delay between recognising that there is an illness and deciding that professional help should be sought, whilst the time taken from that point to actually seeking help is referred to utilisation delay. Different factors contribute to the various stages of delay, including past experience of symptoms, their perceived consequences and concerns about the possible costs, and negative aspects of the treatment and outcome. One condition where delay can have very serious consequences is myocardial infarction (MI), since early utilization of medical care is associated with improved changes of survival. Death following MI typically occurs within a few hours of symptom onset, yet the evidence shows there is a large variation in utilization delay times and that some individuals put themselves at much greater risk as a result (Dracup et al., 1995). This work also shows that symptom severity and interpretation are important since those who perceive their symptoms as indicative of MI are less likely to delay. Problems caused by patient delay over a longer time period are also found with other conditions, including cancer (Facione, 1993), sexually transmitted diseases (Leenars, Rombouts, & Kok, 1993), and mental health problems (Clausen, Pfeffer, & Huffine, 1982).

From the health-care professional's (HCP) perspective it is therefore important to know what symptoms the individual has experienced and the way that these have been interpreted as a basis for understanding the decision to seek help. In view of this, it is noteworthy that guidelines for good patient interviewing in primary care include an encouragement to focus on why the patient has come (Pendleton, Schofield, Tate, & Havelock, 1984). Thus, in addition to eliciting signs and symptoms, doctors are expected to develop an interviewing approach which allows patients to express their own ideas or concerns about their condition. From the HCP's perspective, patients may appear to be seeking help for relatively minor symptoms (e.g., transient pain from indigestion) whereas specific contextual factors (e.g., a close relative with a heart problem) may cause the patient to hold a much more serious representation of their problem.

A further implication for HCP's lies in the issue of reassurance. As will be outlined in Section 8.03.4.1.1, one of the most common patient expectations for a primary care consultation is to be able to have a better understanding of a current complaint (Williams, Weinman, Dale, & Newman, 1995). Since the majority of symptoms will not be found to be indicative of any underlying problem, as the result of a physical examination or diagnostic test, it is not surprising that the HCP will expect this to be sufficient to reassure the patient. For some patients being told that there is no underlying or serious problem is effective in providing reassurance but there is consistent evidence that this is not always so. For a significant minority, there is continued concern about their health status (Channer, James, Papouchado, & Rees, 1987; Lucock et al., in press).

This continued anxiety following reassurance from the HCP may then result in further needless consultations or investigations, and is one of the factors involved in frequent attendance for health care. The key issue here seems to be the nature of the reassuring message which typically consists of reporting that no pathology can be detected and so there is no need to worry (McDonald, Daly, Jelinek, Panetta, & Gutman, 1996). Although apparently comforting from the HCP's perspective, this message only provides negative information and fails to contribute a positive explanation for the symptoms which the patient had or is experiencing. According to Lucock et al. (in press), reassurance in the form of negative information will only provide a short-term reduction of health concern. If symptoms persist or reoccur, then the health concern will also return since the patient still lacks a satisfactory explanation which would enable them to interpret the symptoms as benign. For reassurance to be effective, patients' concerns need to be elicited and appropriate information provided for explaining the symptoms. These findings can be understood in terms of Leventhal's self-regulatory model, which was outlined at the beginning of this chapter. If the patient's cognitive representation of a problem is that it is serious (e.g., heart disease) and the diagnostic test fails to provide any evidence for this, then an adequate alternative explanation and discussion of the symptoms will probably be necessary for the patient to generate a more benign representation and therefore be reassured by the test results.

8.03.4 HEALTH-CARE PROFESSIONAL–PATIENT COMMUNICATION

The consultation between the patient and the HCP lies at the centre of health care. The information which is transmitted during the consultation is very often critical in the formulation of diagnoses and in the organisation of treatment. Effective communication is necessary to ensure not only that the patients' problems and concerns are understood by the HCP but also that relevant information, advice, and treatment is received and acted upon by the patient. Since the late 1960s there has been considerable research on the medical consultation, prompted to a large degree by the fact that there has been consistent evidence that not only are the process and outcome often unsatisfactory for patients but also there is widespread noncompliance with subsequent treatment recommendations. Early research revealed quite high levels of patient dissatisfaction which was often associated with insufficient information, poor understanding of the medical advice, and subsequent reluctance or inability to follow recommended treatment or advice (e.g., Korsch & Negrete, 1972). These early findings showed that many patients complained that they were not given sufficient information about the nature of their problem, the treatment, and the likely outcome. For example, in the Korsch and Negrete (1972) study, which involved mothers taking their children to a paediatric outpatient clinic, about 20% of mothers were not informed clearly about the diagnosis and nearly 50% were uncertain afterwards as to the course of their child's illness. Similar findings have been produced in more recent studies in a variety of health-care settings and it is notable that these problems are unrelated to the length of time spent with the HCP (Korsch & Negrete, 1972).

A related problem involves the use of information, such as medical jargon, by the HCP which the patient misconstrues or cannot understand. Korsch and Negrete (1972) found that jargon was used in about half the consultations in their study. Other studies have shown how much this "communication gap" reflects differences in biomedical knowledge between patients and HCPs. A good example is seen in Figure 3 which shows some data from a study by Hawkes (1974) who investigated patients' and doctors' interpretations of anatomical terms. Not only did this study show that patients' understanding of anatomical terms is often quite different from that of their doctor but also that doctors may also differ in their use of some terms. Another complaint from patients is that the HCP does not appear to be interested in their presenting problem or in their concerns or worries about it and this is associated with lower levels of satisfaction with the consultation (Williams & Calnan, 1991). Moreover, patients often report feeling that they have not been sufficiently involved in the decision-making which may have occurred in the consultation. Hence, Roter and Hall's (1989) overview of research in this area revealed that patient satisfaction was higher following consultations in which the HCP engaged in more social conversation, positive verbal and nonverbal behavior, and partnership building.

The development of relatively unobtrusive audio and video-recording techniques has allowed researchers to investigate the consultation and many studies have analyzed the process of the consultation and attempted to relate process variables or characteristics to outcome. While these studies have identified important themes, they have not always been successful in making clear links between process and outcome (Stiles, 1989). In the absence of simple relations between consultation process variables (e.g., duration or style of consultation) and various outcomes (e.g., satisfaction, adherence, etc.), more recent studies have begun to examine what HCPs and patients bring to the consultation, as well as the importance of contextual factors. As a result, many current frameworks for understanding doctor-patient communication tend to be based on the relations between inputs (i.e., the attitudes, beliefs, expectations, etc. which patient and doctor bring to the consultation), process (the nature of the encounter), and outcome (the short- and longer-term effects on the patient). An example of one such framework is provided by Friederikson (1993) and is shown in Figure 4. An overview of input, process, and outcome factors follows.

8.03.4.1 Input Factors in Communication

Input factors which influence the consultation include not only aspects of the doctor and

patient but also the context and setting in which the consultation occurs. For example, for many primary care consultations in the UK, patients are booked in for 10-minute appointments whereas similar consultations in other countries may typically last two to three times longer. Although longer consultations do not inevitably result in better patient outcomes (Morrell, Evans, Morris, & Roland, 1986), the resulting process may well be different. Similarly, the layout of the consulting room, including the proximity and positioning of the HCP and patient, can also influence the communication process.

8.03.4.1.1 Patient input factors

When considering patient "input" factors which can influence the medical consultation, a number of studies have shown that patients cope with health threats in diverse ways and show consistent differences in how they want to be involved in the health-care process (Krantz, Baum, & Wideman, 1980). These studies also show that patients differ in the amount of information which they would like to receive about their health problem. Similarly, a distinction has been made by Miller, Brody, and Summerton (1988) between "monitors" and "blunters," with the former being more inclined to need and seek out information about their problem and treatment, whereas the latter group prefer consultations in which relatively limited information is provided. This is similar to the repression-sensitisation classification, described in Section 8.03.3.2.3, and reflects the extent to which patients choose to cope with their health problems in a problem-focused or an avoidant manner.

Patients come into the health-care setting with different levels of biomedical knowledge, based on their past experience. There is also consistent evidence that patients have differing expectations for specific consultations (Williams et al.,

1995), and an awareness of these can be helpful in understanding not only why they are seeking help at that time but also in being able to respond effectively to their needs. Following the self-regulatory model, described at the beginning of this chapter, it has been found that patients' illness representations will influence their decision to seek help (Cameron, Leventhal, & Leventhal, 1993) and hence their expectations of the consultation.

Patient expectations have been conceptualized and defined in a range of different ways. In their review of the literature, Thompson and Sunol (1995) have proposed working definitions for four types of expectations that are used frequently:

(i) *Ideal*. This may be referred to as an aspiration or desire;

(ii) *Predicted*. The realistic, practical, or anticipated outcome which therefore reflects what users actually believe will happen in an health care consultation;

(iii) *Normative*. What should or ought to happen and could be equated with what users are told, or led to believe, or personally deduce that they ought to receive from health services; and

(iv) *Unformed*. This state occurs when users are unable or unwilling to define their expectations, which may be because they do not have any, or find it too difficult to express, or do not wish to reveal their feelings, due to fear anxiety, conformity to social norms, etc.

The term "expectations" itself therefore needs to be clearly defined and one reason for the lack of consistency in the research in this area is that many studies have failed to do this. An example of this problem can be seen in a study carried out to investigate the relationship between patients' expectations and HCPs' actions (Webb & Lloyd, 1994). Primary care patients' expectations were measured using questionnaires which asked each patient "How do you think the doctor will be able to help you with your problem?" and instructed the subjects to tick as many of the following actions: "give you a prescription," "refer you to hospital," "give you advice," "help you in some other way." By this method it would not be clear to the patients whether they should respond according to what they themselves want (i.e., "ideal" expectations) or what they merely expect that they will be given by the doctor (i.e., "predicted" or "normative" expectations).

One method of measuring patients' expectations is to categorize their informational needs into distinct categories such as information in relation to aetiology, diagnosis, prognosis, treatment, and social effects (Kindelan & Kent, 1987). However, the measurement of patients' expectations by the simple categorization of needs according to the medical condition can be inadequate since patients may require varying levels of information about the presenting symptoms. The range of psychosocial and medical expectations of primary care patients has been investigated by Good, Good, and Nassi (1983). They have developed a scale (Primary Care Patient Request Scale) from the responses of North American primary care patients and it requires patients to rate the extent to which each item on the scale reflects their needs prior to the consultation. The results of a principal components analysis to investigate underlying components on the types of consultation requests of primary care patients revealed five distinct dimensions: treatment of psychosocial problems, medical explanation, supportive communication, test results, and ventilation and legitimation. A simpler version of this scale, developed by Salmon and Quine (1989), measures four components: explanation and understanding, support, medical treatment, and information-seeking. Using this scale, Williams et al. (1995) have shown that the most common expectation in primary care patients is for explanation and understanding of their problem, with much smaller numbers wanting tests, diagnoses, or support. Thus,patients do not always want or expect diagnosis or treatment since they may be looking to the consultation to gain more understanding of their health problem or may be hoping for support or understanding from their doctor. These prior expectations can be important in determining outcomes, since consultations in which patient expectations are met have been shown to result in greater satisfaction and an increased willingness to follow advice or treatment (Williams et al.).

8.03.4.1.2 Health-care professional input factors

It is important to acknowledge that health-care professionals can vary considerably in the attitudes and beliefs which they have not only about their own and the patient's role, but also about the function and conduct of the consultation. Doctors have been categorized in various ways according to their role perceptions and the extent to which they concentrate on the technical or more psychosocial aspects of patient care, as well as their beliefs about whether patients should be actively involved in the consultation and in decision-making about the management of the clinical problem (e.g., Grol, de Maeseneer, Whitfield, & Mokkunk, 1990). Inevitably, these broad attitudinal differences are reflected in differences in the way in which the consultation is conducted and in other aspects of professional behavior, including decision-making, prescribing, and management of clinical problems (McGee, 1997). Similarly, other HCPs have also been found to vary in their beliefs and attitudes in ways which impact on the way they manage their encounters with patients (Marteau & Johnston, 1990). In clinical psychology, one very obvious HCP input factor is the theoretical orientation of the practitioner, since this can have a major influence on the way in which clients' problems are conceptualized and managed. It has also been shown that personal characteristics of the practitioner can have significant effects on the process and outcome of psychological therapy (e.g., Strupp & Hadley, 1979).

A few studies have attempted to examine the interaction of clients' and therapists' values in psychological therapies (e.g., Kelly, 1990). There is evidence that strong initial differences between client and therapist may have significant negative effects on the early stages of therapy (Kelly & Strupp, 1992) and may be a contributory factor to client dropout (Vervaeke, Vertommen, & Storms, 1997).

Although HCPs undergo a common training and share a common body of knowledge and skills, wide variations in their clinical behaviour have been noted (e.g., Marteau & Johnston, 1990). Part of this variation is a by-product of personality differences and can be seen in differences in interpersonal aspects of clinical practice but part is a reflection of differences in the approach to clinical problems. Some of these are between-individual differences, whereas others reflect factors which can vary within the same individual, such as changing mood, time pressure, and various other contextual influences. In their overview of clinical decision-making, Schwartz and Griffin (1986) point out that there are often substantial disagreements between doctors when interpreting the same clinical information (e.g., X-rays). They also note that doctors may be inconsistent and disagree with their own previous judgements.

Clinical decision-making has been the subject of psychological research for a number of years and there is accumulating evidence of inter- and intra-individual differences in both the process and the outcome (Schwartz & Griffin, 1986). A detailed account of medical decision-making is beyond the scope of this chapter and so what follows is a brief outline of the process together with a focus on some factors which are associated with variation in decision-making performance.

In responding to a new patient, the doctor will first try to solve the problem of what is wrong, based on the various signs and symptoms, and then will have to make a decision about the best approach to treatment. Both these processes occur under conditions of uncertainty and, for much of the time, the doctor's thinking will be based on the use of probabilistic information. The signs and symptoms may be ambiguous and there is often a margin of error in test results. Also, treatment decisions, whether they involve waiting to see what will happen or the prescription of treatment, can involve risks of complications or side-effects.

During clinical decision-making, the doctor is often faced with having to process a large amount of information about the patient and the possible diagnoses and treatment options. In this they are subject to the same limits of information-processing capacity which affect all of us (see Eysenck & Keane, 1995). Thus, there are limits in what can be attended to and how much information can be held in working memory. In view of this it is not surprising to find that all doctors acquire heuristics, or general strategies, for processing diagnostic and treatment information and these are subject to a range of influences.

Kahnemann, Slovic, and Tversky (1982) have described a number of the heuristics which are used during clinical decision-making. These include the representativeness heuristic (decisions based on the similarity between the present situation and known previous ones) and the availability heuristic (judgments made on the basis of information which is most readily available). The influence of representativeness heuristics can be seen in the initial hypotheses which doctors generate for newly presented symptoms and availability heuristics can be inferred from the influence of such factors as recent or emotionally salient events which readily come to the doctor's mind during the clinical judgment process. Christensen-Szalanski, Beck, Christensen-Szalanski, and Keopsell (1983) have demonstrated an availability bias in doctors' estimates of the risk of different diseases since their overestimates of risks were found to be biased by encounters with people with the disease. Similarly, attitudes and beliefs about the doctor's and the patient's role can influence the weighting given to information from patients (e.g., the relative attention given to physical and psychosocial information). The doctor's mood can affect information-processing in a number of ways by directly influencing the speed and accuracy of clinical problem-solving (Isen, Rosenzweig, & Young, 1991) or possibly by constraining access to mood congruent semantic information, as has been demonstrated on more general studies of the effect of mood on cognition (e.g., Power & Dagleish, 1997).

8.03.4.2 The Consultation Process

There are a range of methods and frameworks for analyzing and describing the process of the consultation. One of the broadest distinctions made has been between consultations which are described as patient-centered and those which are HCP-centered, reflecting the extent to which the HCP or patient determines what is discussed (Grol et al., 1990). HCP-centered consultations are ones in which closed questions are used more often and the direction is determined by the HCP, typically with a primary focus on medical problems. In contrast, patient-centered encounters involve more open-ended questions with greater scope for patients to raise their own concerns and agendas. Related to this are consistent differences in the extent to which the HCP responds to the emotional agendas and the nonverbal cues of the patient (see Roter & Hall, 1989). Although there has been a tendency to consider the more patient-centered/emotion-focused approach as preferable, what appears to be more important is for HCP and patient to be in agreement over the nature of the problem and the best course of action (Starfield et al., 1981).

A number of specific methods have been developed for carrying out detailed analyses of the social interaction between HCP and patient based on audio or videotapes or transcripts of the consultations but, as yet, there is no real consensus as to the best method for this. One of the earliest of these was the Bales's (1950) process analysis system which distinguishes verbal statements into those which are task or emotion-focused and then into more specific categories and this approach has been adapted and extended by a number of other investigators (see Roter & Hall, 1989).

With Bales's system, the coding can be carried out using transcripts, audiotapes, or first-hand observations (Bales, 1950; Korsch & Negrete, 1972). Verbal behavior is usually studied, although nonverbal behavior may also be coded. A unit can be as short as a single word or as long as a lengthy sentence; compound sentences are usually divided at the conjunction and sentence clauses are scored as separate units when they convey a single item of thought or behavior. The rationale underlying this approach is that all interpersonal statements can be classified as falling into one of two domains, the task and the socioemotional. Interaction is described in terms of 12 mutually exclusive categories: six "effectively neutral" in the task dimension (e.g., doctor gives suggestion) and six equally divided into positive and negative affective categories in the socioemotional dimension (e.g., doctor agrees or disagrees).

Wasserman and Inui (1983) have noted that a strength of Bales's system is that it deals with both the content and relationship levels of the communication and that it is particularly strong on the relationship level, where it is sensitive to the feelings of each communicator. Moreover, it has been shown to be reliable and applicable in diverse situations. Its main weakness is the treatment of information transfer, that is, the transfer of information from the patient to the doctor as well as in the reverse direction. With this system there is a difficulty in categorising statements that involve both information transfer and affective components. As a result, a number of investigators, including Roter (1977), have modified the system to allow direct coding from audiotapes, assessment of the affective aspects of the clinician's behavior, and a more finely tailored categorisation of the clinical encounter.

An alternative approach, known as the Verbal Response Mode (VRM), has been developed by Stiles (1978) and which classifies each statement made by the HCP and patient into one of eight basic categories (e.g., questions, giving interpretations, etc.). Good overviews of these different approaches are available elsewhere (e.g., Roter & Hall, 1989) and attempts have been made to define a number of more general ways of classifying HCP-patient interactions. For example, one can distinguish between verbal and nonverbal information and, within the verbal domain, six broad categories can be defined: information-giving, information-seeking, social conversation, positive talk, negative talk, and partnership building. From a meta-analysis of these broad categories (Roter, 1989) it has been found that for the doctor, information-giving occurs most frequently (approximately 35% of the doctor's communication) followed by information-seeking (approximately 22%), positive talk (15%), partnership building (10%), social conversation (6%), and negative talk (1%). In contrast, the main type of patient communication consists of information giving (approximately 50%) with less than 10% involving information seeking.

A comparative study of process analysis methods was carried out by Inui, Carter, Kukull, and Haigh (1982). The Bales, Roter, and the VRM system were applied to 101 new patient consultations at a general medical clinic. The outcome measures were patient knowledge, satisfaction, recall of prescribed medications, and compliance. The findings revealed that the explanatory power of the three systems differed. Roter's system was found to explain 28% of the variance in adherence to prescribed medicines, compared to 19% for the Bales system and none for the VRM. The Roter and Bales systems were also better than VRM in explaining variation in satisfaction.

More recently, Roter et al. (1997) have used cluster analysis with the Roter Interactional Analysis System (RIAS) to describe doctor's communication patterns in a study of 127 doctors and 537 patients. Their results revealed five distinct patterns: (i) "narrowly biomedical," (ii) "expanded biomedical," (iii) "biopsychosocial," (iv) "psychosocial," and (v) "consumerist" (see Table 1). They found that "biomedical" approaches were used more often with more sick, older, and lower income patients by younger, male doctors. Patients and doctors completed a satisfaction questionnaire immediately after the consultation. The highest levels of doctor satisfaction were found in those using the consumerist approach and the lowest levels were found in those using the narrowly biomedical approach. In contrast the highest levels of patient satisfaction were found with those who had seen doctors using the psychosocial communication pattern whereas the lowest satisfaction scores were recorded in those who had experienced either of the two biomedical patterns.

A very different approach to process analysis can be found in the studies of Ley and colleagues (Ley, 1988), who have concentrated on the informational content of the consultation and the quality of information provided by the doctor. In particular they have analyzed the content in terms of its level of complexity, comprehensibility, and the extent to which the information is organized. They and others have found that medical information may be too detailed or complex with the result that important information may not be understood or retained by the patient. Ley's studies have shown patients' understanding and recall of the consultation can have a direct influence on treatment adherence or can influence adherence via their effects on satisfaction (see Figure 5).

There is even evidence that patients and doctors may interpret the same information in different ways and this communication gap can occur around anatomical information or other technical terms which are used to describe illness or treatment (see Figure 3).

These various ways of conceptualizing and analyzing the consultation process have given rise to a large number of indices or categories which have been related to outcomes, often in quite a limited fashion. Outcomes, such as patient satisfaction or adherence to treatment, are likely to be determined by a range of factors, reflecting a complex interaction of input, process, and situational variables.

8.03.4.3 Outcomes of Health-care Communication

The efficacy of any communication needs to be evaluated in terms of its effect on outcome. For health-care communication, the ultimate outcome is health but only relatively few studies have measured short or longer-term health outcomes following consultations and these will be mentioned briefly. However, a range of other outcomes have been assessed and these fall into three broad groups, namely cognitive, affective, and behavioral.

8.03.4.3.1 Cognitive outcomes

These can be assessed by evaluating changes in patients' knowledge, understanding, and recall of the relevant information provided in the consultation. Ley and colleagues have carried out a number of careful studies of patient recall and these have been summarized (Ley, 1997). Studies which have assessed how much patients are able to recall from consultations have shown that about half the information is retained but there is considerable range. This variation partly reflects the type of setting and sample used and partly the method which is used to test for recall. There are a number of other factors involved including the content of the information, the patients' prior knowledge, and their level of anxiety. With regard to the content and structure of the message, information which is presented early in the consultation is recalled better (the primacy effect) as are statements which are perceived as being important or relevant. Moreover, if the HCP makes an effort to present information in an organized way based around specific themes (e.g., the nature of the problem, the details of the treatment, etc.), then recall is improved. Not surprisingly, the more information which is presented, the smaller proportion is remembered.

8.03.4.3.2 Affective outcome: patient satisfaction

One of the broadest indicators of the patients' affective response to a health-care consultation is their overall level of satisfaction. Fitzpatrick (1997) has commented that the concept of patient satisfaction is important because it focuses on the need to understand how patients respond to health care. As a result, it is increasingly being assessed in surveys of health-care settings as a marker of quality of care, along with such other dimensions of quality as access, relevance to need, effectiveness, equity and efficiency.

Patient satisfaction is also considered important since it is associated with patient

Table 1 Communication patterns and their frequency of use in primary care consultations.

Type of pattern	*Characteristics*	*Consultations*	*% of doctors*[a]
Narrowly biomedical	Low % of talk on psychosocial topics; high % of biomedical information given by dr. & pt.; high % of question asking by dr.	32	68
Expanded biomedical	High % of question asking by dr.; moderate levels of biomedical and psychosocial exchange for dr. & pt.	33	61
Biopsycho-social	Balance between biomedical and psychosocial exchange in dr. & pt.; fewer questions than in the two biomedical patterns	20	42
Consumerist	High frequency of question asking by pt. and information giving from dr.; low levels of question asking by dr. and of psychosocial exchange	8	23
Psychosocial	Dominated by psychosocial exchange; dr. talk divided between psychosocial and biomedical; high % of pt. psychosocial talk; lowest levels of question asking by dr. & pt.; dr.- very positive and accepting of pt. input	7	19

cooperation (Hall, Roter, & Katz, 1988; Roter, Hall, & Katz, 1987), improved health status (Eraker, Kirscht, & Becker, 1984), and fewer malpractice suits (Vaccarino, 1977). Increased levels of satisfaction have also been found to be related to other important outcomes from the consultation, particularly adherence or compliance with treatment or advice.

Although the concept of satisfaction has good face validity, there is a singular lack of good theory or consensus about its nature or structure. Some approaches are based around the anxiety surrounding illness and equate satisfaction with the adequacy with which this is dealt with by HCPs. Stimson and Webb (1975) have suggested that patient satisfaction is related to the perceptions of the outcome of treatment and the extent to which treatment meets the patient's expectations. This can be related to the self-regulatory model, in that greater satisfaction would be predicted if the patient's own representation of the problem is taken into account by the HCP and if the information which is provided allows the patient to develop a representation of the problem and the treatment which reduces their uncertainty and facilitates their coping, including their adherence to treatment (Leventhal & Cameron, 1987).

More recently Fitzpatrick (1997) has promoted the idea of patient satisfaction as a multidimensional concept, since patients have been found to have differing views about different aspects of their health care, such as the HCP's behavior towards them, the information provided, the technical skills of the HCP, and the access to and quality of the health-care setting. Despite this, there is evidence that the behavior of the HCP is the critical determinant and one which can significantly influence ratings of all the other aspects of health care.

Although patient satisfaction appears to be a relatively straightforward concept, there remain a number of difficulties in measuring it. Results from most satisfaction surveys reveal very skewed data, apparently indicating very high levels of satisfaction across patient samples, particularly amongst older patients (Hall & Dornan, 1988). Part of this problem seems to lie in the reluctance of patients to criticize health-care services and part of it is due to the structure of the questionnaires which have been used to assess patient satisfaction. Comparative studies of different methods have shown variability in satisfaction across measurement approaches. Wide variation in satisfaction scores between three commonly used methods has been reported (Counte, 1979). For example, consistently lower rates of satisfaction are found when the same respondents use a five-point rating scale ranging from "poor" to "excellent" compared to a six-point rating scale ranging from "extremely satisfied" to "very dissatisfied" (Ware and Hays, 1988). In addition, the use of more in-depth methods which require patients to describe their experiences of health from their own perspective, typically give rise to a more critical view (Fitzpatrick & Hopkins, 1993).

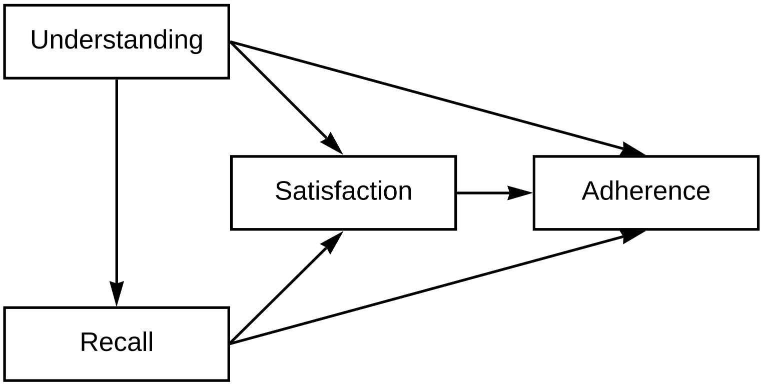

Figure 5 Ley's cognitive model, showing the relations between the patient's understanding, recall, and satisfaction with the consultation and subsequent treatment adherence.

Although these do not provide a quantitative measure, they can be used to highlight areas of dissatisfaction.

There are many patient satisfaction questionnaires that have been developed for use in different health-care settings. For assessing patient satisfaction with the consultation, one of the most widely used measures is the Medical Interview Satisfaction Scale (MISS) (Wolf, Putnam, James, & Stiles, 1978). This scale measures satisfaction with three aspects of the medical consultation. First, it assesses the extent to which the patient feels that the doctor listens, understands, and is interested (affective). Second, it assesses the patient's evaluation of the doctor's competence in the consultation (behavioral) and the third aspect is concerned with the amount and quality of information provided (cognitive).

Bowman, Herndon, Sharp, and Dignan (1992) have identified a number of important structural and measurement criteria for an adequate patient satisfaction scale and have reported that the MISS meets all of these. Moreover, it has good internal consistency and correlates highly with other equivalent measures (Kinnersley, Stott, Peters, Harvey, & Hackett, 1996).

8.03.4.3.3 Behavioral outcome: adherence

The most widely studied behavioral outcome from health-care consultations is reflected in the extent to which the patient adheres to the advice or treatment offered by the HCP. Many consultations result in the prescription of treatment or advice by the HCP and the appropriate adoption of self-care behaviors, including use of medicines, is a key aspect to the self-management of most chronic illnesses. However, many patients fail to do this and low rates of adherence to recommended treatment are seen as problematic in most chronic diseases including asthma (Yeung, O'Connor, Parry, & Cochrane, et al., 1994), diabetes (Glasgow, McCaul, & Schafer, 1986), heart disease (Horwitz & Horwitz, 1993; Monane, Bohn, Gurwitz, Glynn, & Avorn, 1994), cancer (Lilleyman & Lennard, 1996), and kidney disease (Cleary, Matzke, Alexander, & Joy, 1995), as well as in psychological treatments, such as relaxation training for anxiety-related disorders (Taylor, Agras, Schneider, & Allen, 1983).

The incidence of reported medication nonadherence varies greatly from 4–92% across studies, converging at 30–50% in chronic illness (Haynes, Taylor, & Sackett, 1979; Meichenbaum & Turk, 1987). In the area of primary prevention, it has been found that many participants drop out of lifestyle change programs designed to improve diet or reduce health risk behaviors (Dunbar & Agras, 1980). Even patients who have experienced major health problems, such as heart attacks, may show low levels of uptake of rehabilitation programs as well as considerable variation in the adoption of recommended lifestyle change (Petrie, Weinman, Sharpe, & Buckley, 1996). In the area of mental health, there is also evidence of significant rates of nonadherence to various recommendations from HCPs. For example, about half of those undergoing intake in a mental health clinic were found to fail to attend for the first arranged interview and something like three-quarters of psychotherapy patients have been found to drop out by the fifth session of treatment (Phillips, 1988).

There has been a major interest in patient adherence for many years since it has been found that many so patients fail to follow advice or treatment. In view of the importance of this topic, the following section will present an extended overview of it, focusing on the nature of the concept and its causes, as well as ways in which it can be influenced by specific interventions.

Although adherence may be simply defined as "the extent to which the patient's behavior coincides with the clinical prescription" (Sackett & Haynes, 1976), there are several conceptual and methodological issues (Gordis, 1976). It is neither usually possible nor desirable to define nonadherence as an "all or nothing" response in which the patient either completely follows the HCP's instruction (adherence) or deviates from it in some way (nonadherence). For most treatments, the need for total adherence is questionable and this has led Gordis (1976) to define nonadherence as "the point below which the desired preventative or desired therapeutic result is unlikely to be achieved." The percentage adherence necessary to achieve the desired effect varies between treatments and between and within individuals. Many individuals, particularly those with chronic health problems, are required to adhere to a variety of recommendations from their HCPs. For example, diabetic patients are required to take medication, control their diet, and check their feet and blood glucose levels on a regular basis but it has been found that these behaviors are not highly correlated (Glasgow, McCaul, & Schafer, 1987).

Nonadherence behaviors may be categorized as either active or passive. Active nonadherence arises when the patient makes a strategic decision not to take the treatment as instructed. An example of this type of behavior was found among hypertensive patients who believed that they could judge when their blood pressure was high by the presence of symptoms such as stress or headache and thus took antihypertensive medication only when these symptoms were experienced (Baumann et al., 1989; Meyer, Leventhal, & Guttman, 1985). Active nonadherence behavior has been noted among several chronic illness groups including those with asthma (Becker et al., 1978; Woller, Kruse, Winter, Mans, & Alberti, 1993), rheumatoid arthritis (Lorish, Richards, & Brown, 1990), epilepsy (Conrad, 1985), and hypertension (Morgan & Watkins, 1988), and may be particularly influenced by the patients' perception of their problem as well as their level of satisfaction with the HCP and the consultation. From a self-regulatory perspective, the level of treatment adherence may be indicative of a strategic coping response which is entirely consistent with the patient's view of their problem (Leventhal & Cameron, 1987). Thus, patients who believe that their problem will not last for long have been found to be less likely than those with a more chronic timeline representation to adhere to their medication over a long period of time (Meyer, Leventhal, & Guttman, 1985).

Passive nonadherence may be unintentional when the patient's intentions to follow treatment recommendations are thwarted by barriers such as forgetting, and inability to follow treatment instructions because of a lack of understanding or physical problems such as poor eyesight or impaired manual dexterity. Thus, if the quality of communication is poor and patients receive information which is difficult to understand or recall, as has been outlined above, then this makes it less likely that treatment will be adhered to (Ley, 1988).

(i) Measuring adherence

Adherence measures can be divided into two broad categories according to whether the assessment is direct or indirect. Direct measurement entails observing the required adherence behavior such as the ingestion of the drug or by detecting its presence in body fluids. Indirect measures assume ingestion based on proxy evidence such as the patient's report or the number of dosages removed from a container. The strengths and weaknesses of available direct and indirect methods have been reviewed extensively (e.g., Rudd, 1993). At first sight, direct methods might appear to be the best way to assess adherence as other methods do not directly confirm that the medication has been ingested (Caron, 1985). However, these techniques are problematic partly because they may be difficult to carry out and partly because there is not a one-to-one relationship between the amount of medication or tracer taken and the concentration found in body fluids. Furthermore, a major drawback of direct methods is that they are invasive, expensive, of questionable reliability, and provide no indication of the type or time-course of nonadherent behavior. A commonly used indirect method for assessing adherence is to count the number of dosage units left in the container and compare this to the number which would have been left had the patient followed the instructions. This method has the advantages of being technologically simple and inexpensive. However, some studies have shown that pill counts may under-estimate the true level of nonadherence (Kruse, Nikolaus, Rampmaier, Weber, & Schlierf, 1993; Rudd, Ahmed, Zachary, Barton, & Bonduelle, 1990). For example, patients may remove medication for reasons other than to use it. They might give the medication to someone else, or transfer it to another container, or may deliberately discard doses prior to monitoring to create an impression of high adherence.

In the 1990s, technological developments have allowed the incorporation of electronic devices into the medicine container to record the time and date of usage. The major advantage of these devices is that potentially they provide a profile of medication taking rather than simply detailing how much was taken (Kruse et al., 1993; Rudd et al., 1990). However, as with the pill count method, a dose removed is not necessarily a dose taken. Furthermore, if inclusion of the monitoring device changes the appearance of the medicinal product, this will alert the patient to the fact that they are being monitored and may change behavior. Similarly studies assessing adherence to behavioral treatments, such as the use of relaxation tapes, have required the users to keep diaries recording their daily use of the tapes (e.g. Bennett & Millard, 1985) and it is very likely that this self-monitoring process will influence rates of adherence.

One of the most widely used methods of assessing adherence is patient self-report which is held to be a valid indicator of treatment adherence that is practical and useful in a wide variety of research settings (Ley & Llewellyn, 1995; Meichenbaum & Turk, 1987). One problem with self-reported adherence is that questions about medicine taking are often presented at a time and place which is quite distant from the actual event and so reports are subject to recall effects. In particular, even when they admit to nonadherent behavior, people tend to overestimate the extent of their adherence (Ley & Llewellyn, 1995). The accuracy of self-report as a measure of adherence has been assessed by comparison with other, more objective, methods or evaluated on the basis of correlation between self-reported adherence and clinical outcome measures. In the main these studies show that the accuracy of self-report varies according to the type of adherence behavior (e.g., medicine taking vs. lifestyle change) as well as the type of self-report measure used. Nevertheless Morisky, Green, and Levine (1986) have shown that a four-item scale of adherence to antihypertensive medication had acceptable internal consistency and was moderately predictive of blood pressure control at two and five year follow-ups.

(ii) The determinants of nonadherence

The search for causal factors to explain patients' adherence or nonadherence to their recommended treatment or advice has progressed through different phases since the 1960s. Much of the early work focused on the possible contribution of demographic or personality factors, as well as particular characteristics of the treatment or the disease which might influence adherence levels. More recent studies have tended to concentrate on cognitive factors, particularly patients' beliefs and attitudes, since these are potentially modifiable.

In an early systematic review of 185 studies (Sackett & Haynes, 1976), no clear relationship emerged between race, gender, educational experience, intelligence, marital status, occupational status, income, and ethnic or cultural background and adherence behaviors. Moreover, there is little evidence that adherence behaviors can be explained in terms of personality characteristics (Becker, 1979; Bosley, Fosbury, & Cochrane, 1995; McKim, Stones, & Kozma, 1990). Also, the idea that stable sociodemographic or dispositional characteristics are the sole determinants of adherence is discredited by evidence that an individual's levels of adherence may vary over time and between different aspects of the treatment regimen (Cleary et al., 1995; Hilbrands, Hoitsma, & Koene, 1995; Rudd et al., 1990). This limitation also applies to the search for disease and treatment characteristics as antecedents of adherence since there are wide variations in adherence between and within patients with the same disease and treatment (e.g., Cleary et al.; Lilleyman & Lennard, 1996).

One very obvious explanation for nonadherence arises from the poor cognitive outcomes outlined above, particularly poor understanding and recall of information presented in the consultation. Many patients lack basic knowledge about their medication (Al Mahdy & Seymour, 1990; Cartwright, 1994; Eagleton, Walker, & Barber, 1993) but the relationship between this and their adherence is neither simple nor clear-cut. In a review of the adherence literature Haynes (1976) concluded that, although 12 studies had demonstrated a positive association between knowledge and adherence, there were more that had failed to demonstrate a link. Studies conducted since then generally indicate that associations between knowledge and adherence are at best small and inconsistent (Eagleton et al., 1993), and interventions which enhance knowledge do not necessarily improve adherence (George, Waters, & Nicholas, 1983; Haynes et al., 1978).

There is increasing interest in the role of patient satisfaction as a mediator between information provision, recall, and adherence, as would be predicted by Ley's model which was outlined earlier (see Figure 5). In a national UK survey of patients' satisfaction with medicines information, over 70% of respondents wanted more information than they were given (Gibbs & George, 1990). Dissatisfaction with attributes of the practitioner or the amount of information and explanation provided may act as a barrier to adherence by making the patient less motivated towards treatment (Hall et al., 1988).

The emphasis of adherence research since the late 1980s has moved away from attempts to identify stable trait factors which characterize the nonadherent patient to achieving a greater understanding of how and why patients decide to take some treatments and not others (Horne, 1993). Much of this research is informed by psychological theories which conceptualize behavior as the product of cognitions which occur within a social framework and these are described more fully in Chapter 8.01.

The application of social cognition models in research indicates that medication nonadherence may arise from a rational decision on the part of the patient and identifies some of the cognitions which are salient to these decisions. Although there is some variation in the specific type of beliefs which are associated with adherence across studies, the findings show that certain cognitive variables included in the Health Belief Model (HBM) (Janz & Becker, 1984) and Theory of Planned Behaviour (TPB) (Ajzen, 1988) appear to be prerequisites of adherence in certain situations. For example, beliefs that failure to take the treatment could result in adverse consequences and that one is personally susceptible to these effects tend to be associated with higher adherence (Cummings, Becker, Kirscht, & Levin, 1981; Kelly, Mamon, & Scott, 1987; Nelson, Stason, Neutra, Soloman, & McArdle, 1978). Perceived severity of anxiety has also been found to be related to adherence to recommended practice of relaxation training at home (Bennett & Millard, 1985). Additionally, adherence decisions may be influenced by a cost-benefit analysis in which the benefits of treatment are weighted against the perceived barriers (Brownlee-Duffeck et al., 1987; Cummings et al., 1981; Nelson et al., 1978). Other studies, based on the TPB, have shown that the perceived views of significant others such as family, friends, and doctors normative beliefs may also influence adherence (Cochrane & Gitlin, 1988; Reid & Christensen, 1988). Several studies have demonstrated the value of interventions based on the HBM in facilitating health-related behaviors, such as attending for medical check-ups (Haefner & Kirscht, 1970), or using emergency-care facilities in an acute asthma attack (Jones, Jones, & Katz, 1987).

Another cognitive approach which has been used to explain nonadherence is the self-regulatory model outlined at the beginning of this chapter. This model also acknowledges the importance of symptom perception in influencing illness representations and adherence as a coping behavior. Confirmatory evidence for this is provided by findings from a study of patients with diabetes who used perceived symptoms to indicate their blood glucose levels and to guide self-treatment (Gonder-Frederick & Cox, 1991). Unfortunately patients' beliefs about their symptoms, and estimations of their own blood glucose levels, were often erroneous and resulted in poor diabetic control. Further evidence of the importance of illness representations was obtained by Meyer et al. (1985) who noted a clear relationship between illness representations and behavior in their study of patients with hypertension. Patients who believed that their hypertension was an acute condition were more likely to cease taking antihypertensive medication than those who believed it to be a chronic condition. This study also showed that patients' representations of their illness often conflicted with the medical view and provided an insight into the effects of mismatch between the patients' representations and those of their doctor. In a group of 50 patients who had continued in treatment, 80% agreed with the statement that "people cannot tell when their blood pressure is up." However, 92% believed that they could tell when their own blood pressure was raised by monitoring symptoms such as tiredness, headache, and stress. Patients who believed their anti hypertensive medication improved symptoms were more likely to take it. A striking example of this was provided by five out of 17 patients who believed that their medication affected symptoms. These patients took their antihypertensive medication only when they judged their blood pressure to be raised. The patients had understood and accepted the abstract medical view of hypertension as an asymptomatic condition but their concrete experience or symptoms caused them to hold contrasting beliefs and to behave according to these.

Illness perceptions have been linked with a range of adherence-related behaviors other than the use of medicines. These include various self-management behaviors, such as dietary control and blood glucose testing in diabetes, attending rehabilitation, and the adoption of various lifestyle changes following myocardial infarction. A study of noninsulin dependent diabetic patients, has shown that personal models of diabetes are related to dietary self-management and to exercise adherence but not to the more medical aspects of control, such as blood glucose testing and taking medication (Hampson, 1997). Similarly, in a prospective study of patients following first-time myocardial infarctions (MI), Petrie et al. (1996) have found that specific illness perceptions are predictive of different post-MI behaviors. They found that attendance at rehabilitation, which is prescribed for all patients, was predicted by the strength of their belief in the cure/control of their MI whereas return to work depended more on the extent to which the patient saw their MI as having less serious consequences

In addition to studies of the role of illness beliefs, there is a small body of work which has examined people's beliefs about medicines and the ways in which these could influence adherence (Britten, 1994; Conrad, 1985; Donovan & Blake, 1992; Morgan & Watkins, 1988). The negative beliefs about medicines identified in these studies appear to be common across several illness and cultural groups and include worries about the potentially harmful effects of medicines and about long-term dependence on them. However, there are only a few studies which have assessed medication beliefs quantitatively and they have used different questionnaires or have investigated medication beliefs in the broader context of views about the practice of medicine (Echabe, Guillen, & Ozamiz, 1992; Marteau, 1990). Some studies have assessed peoples' ideas about medicines in general, whereas others have focused on specific medication prescribed for a particular illness.

Research by Horne (1997) indicates that four "core-themes" or factors underlie commonly held beliefs about medicines. Factor analysis of a pool of belief statements revealed two broad factors describing peoples' beliefs about their prescribed medicines: their perceived necessity for maintaining health (specific-necessity) and concerns based on beliefs about the potential for dependence or harmful long-term effects and that medication taking is disruptive (specific concerns). Two factors were also found to describe peoples' beliefs about medicines in general. The first relates to the intrinsic properties of medicines and the extent to which they are harmful, addictive substances (general-harm) and the second factor comprises views about whether medicines are overused by doctors (general-overuse).

Peoples' views about the specific medication regimen prescribed for them were found to be much more strongly related to adherence reports than are more general views about medicines as a whole. Moreover, an interplay was found between concerns and necessity beliefs which suggests that people engage in a risk-benefit analysis and consequently attempt to moderate the perceived potential for harm by taking less. Patients with stronger concerns based on beliefs about the potential for long-term effects and dependence reported lower adherence rates, whilst those with stronger beliefs in the necessity of their medication reported greater adherence to medication regimen (Horne, 1997).

8.03.4.3.4 Consultation outcomes: an overview

The cognitive, affective, and behavioral outcomes of the consultation are very closely linked and can influence each other. Patient satisfaction, understanding, and beliefs can play a major role in influencing adherence with treatment or advice, which is obviously important in situations where nonadherence results in adverse health consequences. Since there is evidence of high levels of nonadherence, this can clearly affect other outcomes including health and well-being. The latter have not often been studied as communication outcomes but there are a number of studies which demonstrate positive effects on patients' health and well-being arising from positive experiences in medical consultations (Stewart, 1995). These have focused on psychological states such as anxiety as well as changes in specific physical variables such as blood pressure and blood glucose control. Some of the most impressive findings here have been found in the patient-intervention studies, which are described below.

8.03.4.4 Improving Health-care Communication

In addition to increasing our understanding of health-care communication and its central role in health-care delivery, some research findings have also provided insights for developing interventions to improve the quality of communication. The majority of these have been aimed at improving the communication skills of health-care students or practitioners at various stages of training but a few have been targeted at patients, to enable them to get the most from a consultation. Both types of intervention approach will be outlined.

Communication skills training is now regarded as a fundamental part of the curriculum for medical, nursing, and other health-care students but this varies considerably in terms of the amount and type of teaching and the stage at which it is taught. Typically, students are provided with an overview of the basic skills of "active" listening which facilitate patient communication. At a basic level these include the importance of developing good rapport and the use of open-ended questions early in the consultation, appropriate eye-contact and other facilitatory responses to help the patient talk, together with the ability to summarize and arrive at a shared understanding of the patients' problem. These skills can be taught in a number of ways but the successful courses inevitably involve active learning, using role-plays with simulated patients, as well as real patient interviews (see Kendrick, 1997; McManus, Vincent, Thom, & Kidd, 1993). Feedback is important to identify problem areas as well as indicators for improvement, and increasing use is made of videotape for this purpose. There is consistent evidence that this type of training can result in clear improvements in basic communication skills which are maintained for a number of years (Maguire, Fairburn, & Fletcher, 1986).

In addition to these basic packages, it is also necessary for health-care students to learn how to communicate about sensitive or difficult areas of clinical practice, including dealing with distressed patients or relatives and giving "bad news." Research in this area, using tape-recorded consultations, has shown that doctors tend to give detailed information rather than find out and respond to patients' concerns and informational needs. As Maguire (1997) notes, this avoidance of patients' worries can have negative effects in the short and longer term. An immediate consequence is that patients may remain preoccupied with their own concerns and fail to take in information or advice. They may also selectively attend to negative phrases or messages and be unresponsive or misconstrue more positive or neutral information. Maguire (1997) provides the example of a surgeon who informs a recently diagnosed cancer patient that radiotherapy will be given "to mop up any residual cells," and then adds "I am sure that we will eradicate your cancer." When questioned afterwards, the patient only recalled the phrase "residual cells" and became very distressed since she thought that this meant that the cancer would spread through her body.

There were are various reasons why doctors and other health-care professionals may be poor at "bad news" communication and these include lack of training, fears about the effects of exploring patients concerns, lack of support, and a desire to protect their own emotional well-being. Some of the training packages which have been developed have taken these factors into account and provide sufficient time for the learners to explore and get feedback on different strategies, using role-play situations. Many of the component skills are those which are part of any communication training package, such as those outlined earlier in this section. The key first step is to ensure that this communication takes place in an appropriate environment and needs to start with the patient, exploring what they have been told and what they think and feel about their condition. If will often be necessary to take time to provide the patient with the information which they want, letting patients proceed at their own pace and allowing information to be assimilated. The other key skills involve developing the ability to recognise distress and allow this to be expressed without feeling discomfort or providing unrealistic reassurance (Maguire, 1997).

There is growing evidence that the way bad news is presented to patients can have major effects on the patient's perception of their condition and on subsequent coping and adjustment (Fallowfield, Hall, Maguire, & Baum, 1990). Effective training of health-care professionals in this area can have significant effects on the quality of health care for patients with serious or terminal conditions. In addition to improving the HCP's communication skills, there is also considerable scope for providing patients with more useful information, including tape-recordings of their consultations.

Since the 1980s, there have been a number of interesting interventions aimed at patients. Generally, these have involved interventions for patients prior to a consultation in order to increase their level of participation, particularly to ensure that their own concerns are dealt with and that information provided by the doctor is clearly understood. A successful development of this approach can be seen in the work of Greenfield, Kaplan, and Ware (1985) who used a preconsultation intervention lasting 20 minutes for hospital outpatients who were helped to identify their main questions and encouraged to ask these in the consultation. Compared with control patients, these patients participated more actively in the consultation and this was also associated with better long-term health outcomes, including lowered blood pressure in hypertensives and better glycaemic control in diabetic patients. These interventions can be quite time-consuming and a number of researchers have explored the possible efficacy of simpler patient-based interventions, such as the use of preparatory leaflets (e.g., McCann & Weinman, 1996), but these have not shown such significant effects in changing the process or outcome of consultations.

Finally, mention should be made of two specific patient-based approaches which have been very successful. The first by Ley and colleagues (see Ley, 1988) involved hospital patients and an additional short visit which allowed them to ask for any information to be clarified. Compared with control groups, these patients had a much higher level of satisfaction with communication, indicating that effective interventions need not be of complex or time-consuming. Hogbin and Fallowfield (1989) describe another simple intervention which consisted of making a tape-recording of the "bad news" consultation and allowing patients to take away and keep the tape. Since this type of consultation is often very distressing, patients may often find it very difficult to take in all the information. Thus, it was found that patients welcomed the use of these tapes as something which they could go back to and which others could also listen to.

The importance of providing patients with access to information in various forms, which can be discussed and shared with family and friends, is very pertinent in this area of health. In this respect it is interesting to note the development of patient support groups and information exchanges using the "internet" (Davison & Pennebaker, 1997). Providing patients with access to others with similar or related medical conditions may result in very important gains in communication. For example, patients may be able to locate and communicate with others who have very similar experiences and circumstances, which may not only have a supportive function but may also provide ways of sharing and coping with many of the problems which are experienced.

8.03.5 HEALTH CARE IN HOSPITALS

This section of the chapter will focus on a range of psychological aspects of health care in hospital settings. It begins with a general consideration of the psychological consequences of admission to hospital and is followed by a brief outline of some of the psychological problems associated with the hospitalization of younger children. Then there is a selective overview of particular hospital treatments such as intensive care and haemodialysis which can produce specific emotional reactions due to the limitations and demands they impose on patients. Similarly, many medical procedures are found to be painful or distressing and a number of psychological interventions, which have been devised to help patients cope with these, are outlined in the final part of this section.

8.03.5.1 Psychological Effects of Hospitalization

Hospital patients vary in many ways including their age, personality, and social circumstances, as well as in the severity of their health problems and the duration of their stay. Also, their experience in hospital will vary greatly and this inevitably means that there are difficulties in attempting a general discussion of the impact of hospital admission. Some specific issues concerning children are presented separately but the following account is intended to convey some of the more general factors which have been identified. The psychological reactions which are described may reflect not only a response to hospitalization but also to the illness itself.

8.03.5.1.1 Physical and social environment

One obvious feature of hospital life which involves a considerable change for the patient is the physical environment. Although a number of studies have demonstrated positive and negative effects of the built environment on psychological well-being and health (Spencer & Baum, 1997), there are relatively few studies which have directly investigated how the physical environment of the hospital affects the patient's condition. The hospital environment has been identified as one of a range of stressors which people experience in hospital (Koenig, George, Stangl, & Tweed, 1995). Even such factors as the nature of the view from the patient's bed have been found to affect recovery. For example, Ulrich (1984) found that patients with a window view of trees had a better postoperative recovery (i.e., fewer complications, less analgesia, better adaptation, shorter length of stay) than patients recovering from the same type of surgery but whose hospital window looked out on to a brick wall.

The hospital environment is frequently seen to be drab, clinical, impersonal, and cold by patients. Whereas in the outside world the individual operates with a strong sense of personal space, which is the amount of space necessary for optimal social behavior, in hospital this space is being constantly invaded as part of the daily routine. The daily routine itself is one which is very likely to be very different from life at home and therefore may require considerable adjustment. It is not therefore surprising to find that studies, which have compared home-treated and hospitalized patients with the same condition, have shown less psychosocial distress in those remaining at home (e.g., Oldenburg, Macdonald, & Perkins, 1988).

Enforced life-style changes have also been identified as a key hospital-based stressor in the Hospital Stress Index (Koenig et al., 1995). Admission to hospital removes individuals from a familiar, well-ordered world and places them in an environment which is different in every respect. In hospital they are likely to be totally dependent on others for most basic functions such as washing and feeding. Usually they will be restricted to one place, surrounded by totally new people, whose skills are now of vital importance to them, and it is significant that developing good relations with hospital staff is not only an important factor in adaptation to hospital life but can also be a potential source of stress for patients (Koenig et al.). Other hospital stressors which have been identified by an older measure, the Hospital Stress Rating Scale (Volicer & Bohannon, 1975), include worries about aspects of communication with staff as well as concerns about investigations and treatment, which are discussed in more detail below.

On the positive side, studies by Kulik and Mahler (1987) and Kulik, Mahler, and Moore (1996) have demonstrated the importance of social contact in the recovery of patients following surgery. These studies have focused on the effects of having a preoperative room-mate on the anxiety and recovery of surgical patients. In the early study they compared the effects of sharing a room either with a patient who was also about to undergo cardiac surgery or with one who had already had the same operation. The results showed clear beneficial effects of sharing a room with someone who was recovering from surgery. The patients who had postsurgical room-mates were less anxious prior to surgery, engaged in more postsurgical physical activity, and were discharged sooner (Kulik & Mahler, 1987). In a more recent variation on this study, two further variables were investigated, namely having a room-mate or being on ones own and having a room-mate who was about to undergo or had gone through same type of operation. In addition to replicating the earlier findings with respect to the advantage of sharing with a postsurgical patient, it was also found that it was advantageous to share with a postsurgical patient who had undergone the same type of surgery and that those who were in rooms on their own had the slowest recovery (Kulik et al., 1996).

8.03.5.1.2 Communication in hospital

In addition to the general stresses associated with hospital admission, some of the fear and anxiety which is found in many hospital patients may stem from the uncertainty and lack of information which they may have about the nature of their illness and its treatment and prognosis. There are a number of studies of hospital patients which show clearly that they are greatly dissatisfied with the communications aspect of hospital life (e.g., Ley, 1972). These studies indicate that about 40–50 % of hospital patients are critical of the communication aspects of their stay. Many of the communication problems which were discussed in the earlier part of this chapter (see Section 8.03.3) are also seen in hospital settings.

There is also evidence that hospital patients are often diffident in this respect and are unwilling to ask for information. The diffidence which seems to underlie patients' reluctance to complain or ask for information has been the subject of psychological study and it would appear that patients enter hospital with ideas about how they should behave. Lorber (1975) has identified three categories of patient which she labeled "good patients" (about 50% of her sample), "average patients" (about 25%), and "bad patients" (about 25%) on the basis of the ratings of their medical staff. Patients who were labeled "good" were ones who had straightforward medical problems, were uncomplaining and docile, who took up minimal staff time, and showed uncomplicated recovery. The "average" group were rather similar except they had some problems, but these were manageable. The "bad" group consisted either of patients with serious conditions or those without serious conditions but who complained and put extra demands on the staff as a result.

Interestingly, these patterns of behavior could be detected from interviews with patients about their views of the patient's role at the time of their admission. Thus, it would appear that many patients enter hospital with the expectation of being in a relatively passive role and the pattern of life in hospital actually reinforces this, sometimes to the point of helplessness. Taylor (1979) describes how helplessness can develop when questions go unanswered and desires for attention are not met. As a result "good" patient behavior may actually be detrimental to recovery since it prevents patients from taking an active role in their health care. Moreover "bad" patient behavior can be seen as a reaction against helplessness and an attempt to gain a degree of control, and hence could be thought of as a healthier response.

Fortunately, these problems do not appear to be insurmountable. For example, Ley, Bradshaw, Kincey, and Atherton (1976) conducted a study of hospital patients on three wards of a general hospital. In one ward there was an extra visit made to patients every 10 days, in which attempts were made to ensure that they had understood what they had been told. These visits were relatively brief and only concerned with clarifying existing information rather than raising new issues. The second ward essentially comprised a control group, who received an extra visit to discuss their welfare, food, and so on and not to clarify information. Patients in the third ward in the study received no extra visits. The results showed that 80% of patients who had received the informational visit were satisfied with the communication received, which was approximately twice the level of satisfaction with communication found in the other two groups.

In addition to these general psychological impacts of hospitalization, there may be specific problems or demands which occur either as the result of the particular health problems or the type of treatment which the patient has to undergo. An example of the way in which the patient's health problem may influence their experience of hospital care can be seen in some of the studies of patients with AIDS who may experience negative attitudes from staff or other patients. These negative attitudes are closely linked with the blaming attributions which staff or patients may have for the cause of AIDS. In a survey of 270 AIDS patients being treated in either special care units or integrated in more general hospital settings, specific stresses were reported by those in the integrated units (Van Servellen, Lewis, & Leake, 1990). Whereas both groups were bothered by the same range of general stressors identified above, particularly loss of independence, separation from loved ones, and problems with medicines, those who were in integrated settings more frequently experienced and were upset by factors associated with ambiguity about their care and their medical condition. Moreover, these patients also reported higher levels of stress associated with feelings of abandonment and impersonal or discriminatory treatment. A number of studies of HCPs have revealed evidence that their attributions of patient blame for their condition can have direct influences on their attitudes to the care of the patient as well as their approach to and involvement with them. Broadly, it has been shown that where staff see patients as instrumental in having brought about their own condition through their own behavior or neglect, then they may be less committed, motivated, and sympathetic towards them (Marteau & Riordan, 1992).

8.03.5.2 Children in Hospital

In many countries approaching 50% of children will have spent a period of time in hospital and for those with chronic conditions many have to spend longer periods or visit repeatedly over a number of years. There is evidence that children's reactions to illness and hospital treatment can be quite distinct and that the psychological and social consequences of separation from home can produce quite specific problems. Older studies of the emotional reactions of children to hospital (e.g., Illingworth & Holt, 1955) showed that admission to hospital was often very distressing for them, particularly the younger ones, but the situation has improved over the years. Since that time various recommendations have been put forward and, to some extent, implemented to allow greater access by parents to their hospitalized children. These have included increased flexibility in visiting arrangements as well as a greater provision of overnight accommodation for parents.

Adaptation to hospital life will depend greatly on the age and personality of the child as well as on the family and their reaction to the child, to disease, and to hospitals. When they occur, emotional problems in hospital are much more prevalent in younger children, particularly up to and around the age of four. Older children are more amenable to explanation and are usually less distressed by separation from home and by being surrounded by strangers. A more extensive discussion of children's responses to health issues and health care can be found in Chapter 8.27.

There are a number of specific psychological problems associated with the hospitalization of children. The problems would appear to stem from three sources:

(i) The social separations and disruptions incurred by admission to hospital;

(ii) The emotional response to the clinical problem; and

(iii) The lack of preparation for hospital life and the investigations and treatments to be carried out.

The more long-term effects of hospitalization on children suggest that some of the traumatic effects reported in early studies may have been overstated. Follow-up studies of hospitalized children indicate that serious problems are only found in children who had psychological problems prior to admission or who come from difficult families (La Greca & Stone, 1985). Studies of preparation of children for hospitalization also show that different types of preparation appear to be suitable for children of different ages and with different amounts of prior experience (see Schmidt, 1997 for an overview).

8.03.5.3 Psychological Aspects of Specific Hospital Treatments

In the same way that physical illness imposes physical and social limitations on the individual which can give rise to psychological reactions, some treatments are also very restricting and have been found to cause emotional and behavioral changes. In particular, a number of studies have been made of patients in specific treatment settings such as intensive care units (ICUs), coronary care units (CCUs), and haemodialysis. Although these treatment environments can give rise to specific stressors, they also offer challenging opportunities for psychological interventions.

Experimental work with healthy volunteers has shown that long periods of sensory deprivation or sensory overload will often give rise to a state characterized by increased wakefulness, disorientation, and visual hallucinations (Goldberger, 1982) These states have also been found in some patients who are being treated in ICUs since they may be exposed to long periods of sensory deprivation produced by monotony and immobilization, sometimes interrupted by periods of overstimulation, as well as sleep deprivation. It is claimed that the observed "ICU psychosis" is the result of all these factors on an individual who is already fearful of his or her life because of a serious physical illness. Fortunately, these dramatic psychological responses gradually disappear when normal amounts of sensory stimuli and sleep are restored by returning the patient to a normal hospital environment. More important, these changes can be avoided if the ICU contains a more varied sensory environment and with good contact with visitors and staff. For example, Keep, James, and Inman (1980) have compared patients in ICUs with and without windows, and found that those in the windowless units were less well oriented during their stay and had a less accurate recall of their length of stay afterwards. In addition to these general problems associated with the ICU, other studies have assessed the degree of stress experienced by patients, staff, and visitors. For example, in a study of a surgical ICU, patients rated their level of stress from a wide range of events which occurred (Pennock, Crawshaw, Maher, Prue, & Kaplan, 1994). The ratings were made shortly after their transfer from the ICU and indicated relatively minimal distress associated with many events with exception of being intubated and not being able to communicate. For patients' relatives there is evidence that they find the time spent by the patient on life support in the ICU particularly worrying. During this time they experience considerable fear and uncertainty but this can be resolved by seeking information and the use of other resources (Jamerson et al., 1996). For staff working in this climate, it is assumed that greater levels of work-related stress will be experienced, compared with other hospital personnel. However, the evidence on this is ambiguous and some studies have shown that ICU staff show a more positive attitude to their work and work environment than equivalent non-ICU staff (Boumans & Landerweerd, 1994).

In the context of coronary care, a number of studies have identified possible areas for psychological intervention in facilitating the recovery of patients in CCUs. Using a self-regulatory framework, one study has shown that patients with myocardial infarction have clear beliefs about the cause, timeline, consequences, and controllability of their heart condition during the acute phase of their hospital stay in the CCU. Moreover, these beliefs appear to be associated with subsequent attendance at cardiac rehabilitation and with later adaptive changes, such as return to work and social functioning (Petrie et al., 1996). In addition to these cognitive processes, there is also good evidence that patients' mood states at the early stages of recovery are related to longer-term physical and psychological well-being (Frasure-Smith, Lesperance, & Talajie, 1995) and there is now increased awareness of the ways in which appropriate care during the hospitalization phase of treatment can promote adaptive coping and recovery (see Bennett, 1994).

In contrast to the acute psychological restrictions and demands of intensive or coronary care, some patients are subject to much more chronic restrictions as part of their treatment. Many patients with renal failure are required to spend a considerable amount of time on renal dialysis machines, either in hospital or at home. These patients have a uniquely dependent relationship not only on their dialysis machine but also with the staff involved in their treatment. Dialysis can have major effects on an individual's psychological and social functioning, particularly giving rise to vocational impairment, reduced sexual activity, and mood changes (Oldenburg et al., 1988). In addition to the physical limitations and demands of dialysis, the patients are also faced with the need to adhere to strict recommendations regarding diet and fluid consumption, as well as complex medication regimens. Nonadherence can be a key issue in renal failure and the range of adherence-related factors outlined in an earlier section are very pertinent for patients on dialysis.

One finding which emerges from studies of patients on renal dialysis is that psychological dysfunction at an early stage is a predictor of longer-term adjustment. This means that it is not only vital that good psychological care is available during hospital treatment but also that "at risk" individuals can and should be identified at an early stage in order to anticipate later difficulties. It is noteworthy that comparative studies of patients on hospital or home-based dialysis show that the home-treated individuals show much less social dysfunction (Oldenburg et al., 1988). Part of this may well reflect the patient selection criteria for hospital and home dialysis, with more "problematic" patients tending to be treated in the hospital setting. However, part of this may also reflect the additional negative effects of hospitalization, outlined earlier, superimposed on the specific limitations and demands of dialysis.

The most commonly reported psychological difficulties found in patients on renal dialysis are depression and anxiety but the extent of this is unclear. There is a range in the reported prevalence of depression from 10–100% (Levy, 1994) and this variation is partly due to the different criteria and measures used (see Kaplan De-Nour, 1994). Another reason stems from the similarities between the physical effects of renal failure, such as fatigue, apathy, and sleep difficulties, and the symptoms of depression. Despite these methodological problems, there do appear to be a number of aspects of dialysis which can give rise to psychological distress. For example, Devins, Binck, Hollomby, Barre, and Guttman (1981) have identified the constant threat of death, dependence on the dialysis machine, medical staff, and the stringent dietary and liquid restrictions as key factors in the widespread feelings of helplessness and lack of control. Patients' perceptions of control over their treatment have been found to interact with treatment experiences and illness severity in determining mood outcomes (Christensen, Turner, Smith, Holman, & Gregory, 1991). A belief that one's health is subject to personal control has been found to be associated with lower levels of depression in people who had only been treated by dialysis whereas, for those who had returned to dialysis following a failed kidney transplant, higher control beliefs over health were associated with greater depression.

In line with self-regulatory theory, patients representations of their kidney disease, including their control perceptions, would be expected to influence coping and other outcomes, including treatment adherence (Horne & Weinman, 1994). Studies by Christensen, Benotsch, Wiebe, and Lawton (1995) have demonstrated that problem-focused types of coping were associated with better adherence to fluid intake restrictions when these coping strategies were used in response to stressors arising from a relatively controllable aspect of dialysis. For those stressors which patients perceived as less controllable, emotion-focused coping strategies were associated with better levels of adherence.

8.03.5.4 Stressful Medical Procedures in Hospital

In addition to the generally stressful effects of hospital admission, there is a range of medical procedures which can give rise to considerable discomfort and anxiety. These include specific investigative procedures such as barium X-rays (Allan & Armstrong, 1984), endoscopy (Johnson, Morrissey, & Leventhal, 1973), and cardiac catheterization (Kendall et al., 1979) which may not only be uncomfortable and sometimes physically distressing but which also carry the threat of uncovering a serious medical condition (Weinman & Johnston, 1988). The other obvious "event" in hospital which has been found to produce significant psychological effects is surgery. The psychological impact of surgery will partly depend on the procedure, the condition, and the likely outcome as well as on such psychological factors as the patient's expectations and coping style and the quality of communication.

The way in which a patient reacts to a medical procedure can also have a significant influence on the outcome, particularly in recovery from surgery. Patients who show the highest presurgical levels of stress response will also tend to experience adverse psychological reactions postsurgically and will be more likely to show poorer physical recovery (Johnston, 1986). These patients have been found to request more analgesia, show more postsurgical complications, and tend to recover more slowly with delays in discharge, as compared with less anxious or stressed patients.

8.03.5.5 Psychological Interventions for Stressful Medical Procedures

Since studies have shown a relation between patients' psychological state and their recovery, it has been recognized that there could be considerable gains from providing a psychological intervention designed to reduce or minimize the psychological impact of a medical procedure. There is a range of interventions which have been used to prepare patients for surgery or other stressful procedures in the hospital setting. In broad terms, they can help by providing the patient with information to reduce the uncertainty of the event, or with specific behavioral or cognitive skills to help with some of the discomfort or pain Mathews and Ridgeway (1984) have provided a clear overview of the various preparations and these are summarised in Table 2.

Procedural information is probably the most widely used approach and consists of providing information about the various procedures which will take place before and after the operation. In short, it involves a description of what will be done to the patient at different stages pre- and postoperatively. Sometimes this information is also accompanied by an explanation of the purpose of each of the procedures which are described. Thus, it provides the patient with a map of the events which will occur and, in doing so, can reduce the uncertainty of the whole process.

Sensory information describes what patients are likely to feel, particularly during the immediate postoperative pain period. The important point here is to provide matter of fact or benign interpretations of the sensations so that the patient can recognize them as part of the expected postoperative process. Thus, the patient who can recognize postoperative pain as an expected sensation caused by the incision and reflecting the healing process will be far less likely to be distressed than someone who has not been prepared for the pain and who may think of it as problem or a complication of the surgery.

Contrada, Leventhal, and Anderson (1994) have outlined an interpretation of the benefits of sensory and procedural information from the perspective of the self-regulatory model. They view the sensory preparation as providing a script which describes internal sensations and the procedural preparation as a script providing the objective external events involved in surgery. They maintain that it is the availability of the script which reduces uncertainty and worry for the patient. More specifically, Leventhal (1985) has argued that sensory information should be particularly helpful since it focuses on potentially threatening sensations (e.g., pain, discomfort) with the aim of ensuring that these are processed as nonthreatening or less threatening. However, evidence on the efficacy of both types of preparatory information indicates that procedural information is at least, if not more, effective in producing favorable outcomes (Johnston & Vogele, 1993, see below).

Behavioral instructions are also commonly provided and describe different behaviors which will help before, during, and after surgery. These include instructions about ways to cough and move in bed which will reduce the likelihood of pain associated with these movements. Other behavioral instructions such as deep breathing and ambulation exercises may also reduce the incidence of pain or complications as well as facilitating recovery.

Modeling is based on the use of filmed models who can be seen undergoing the same procedure as the patient. Following Bandura's social learning theory (Bandura, 1986), modeling or the observation of others completing a difficult or stressful task can serve to increase the individual's sense of self-efficacy for managing the same task. Two main types of model have been investigated: (i) mastery models who are shown dealing with the task with ease and ability, and (ii) coping models who are shown as having some anticipated concerns but who nevertheless are able to overcome these and cope with the procedure. The coping type of model has been found to be a more effective preparation for children undergoing surgery. For example, in a study of children about to be innoculated, Vernon (1974) has compared a group of children who saw a preparatory film which was realistic (the child in the film is seen to experience short-lived, moderate pain and emotion) with a group who saw an unrealistic film (no pain or emotional expression) and a group who saw no preparatory film. The realistically prepared group were found to experience least pain when receiving their injections. These methods have been more widely used with children than with adults, particularly since it may be difficult to provide children with sensory or procedural information or behavioral instructions in a meaningful way.

Relaxation-based interventions can involve a number of different techniques. These may involve the use of deep breathing, progressive muscle relaxation, or, less frequently, hypnosis. Relaxation can be used both to provide a general preparation involving anxiety-reduction and to give a specific skill which can be used postoperatively for dealing with pain or discomfort.

Cognitive coping procedures focus on patients' concerns and fears about the surgery and provide ways of dealing with them in one of two ways. First, they may make use of coping strategies which the patient has used successfully in the past for dealing with stressors, enabling the patient to rehearse and apply these in the surgical context (Langer, James, & Wolfer, 1975). The second cognitive approach involves dealing with negative thoughts by distracting attention from them and by focusing on positive aspects of the surgery and repeating positive self-statements (Ridgeway & Mathews, 1982).

The efficacy of these interventions has been evaluated by examining their effects on a range of postsurgical outcomes, including anxiety, pain, and use of pain medication, length of stay in hospital, and various indicators of recovery. All the interventions have been found to be successful in improving at least one aspect of outcome and the majority have a positive impact on many of the outcomes. The different interventions have been examined systematically in a meta-analysis by Johnston and Vogele (1993) and their findings will be outlined briefly. The largest recovery effects were obtained for pain, negative affect, and physiological indices

Table 2 Psychological preparations for stressful medical procedures.

Type of preparation	*Example*
Procedural information	"After the operation, you will be taken to the recovery room, where specialist staff will care for you"
Sensory information	"It is normal to feel a sharp, burning sensation along the line of the incision"
Behavioral instructions	"You should try to cough four times each morning and afternoon/evening to keep your chest clear"
Modeling	"This film shows someone like you coping with the procedures that you will be experiencing"
Relaxation	"Try to breathe deeply and concentrate on relaxing the muscles of your body whenever you feel tense"
Cognitive coping	"You say that you are worried about the anaesthesia. Try to think of ways in which you could make those thoughts more positive"

Source: Mathews & Ridgeway (1984).

of recovery but there was considerable variation in the magnitude of these effects. Smaller but more consistent advantages of psychological preparation were found on pain medication and length of hospital stay. The interventions which had the most widespread overall effects on all the outcomes were found to be procedural information provision and behavioral instructions. Relaxation was also found to have beneficial effects on the various outcomes. Whereas Mathews and Ridgeway (1984) had indicated that cognitive coping interventions were most likely to have the greatest efficacy, the meta-analysis results show that their effects appear to be restricted to specific outcomes. Thus, cognitive interventions have been shown to have positive effects on negative affect, pain and use of pain medication, and clinical recovery but do not appear to result in shorter lengths of stay or in improved physiological indices or behavioral recovery. Surprisingly, in view of the importance attached to patient evaluations of health care, only a few studies have examined the effects of these interventions on patient satisfaction but these show quite positive results, indicating that patients view them as acceptable and helpful.

In summary, there is considerable evidence to indicate that different types of psychological preparation can not only reduce the anxiety, stress, and pain involved in many medical procedures, but also that there are considerable related benefits (e.g., less analgesia, better recovery, faster discharge, etc.). Although the above outline of approaches provided separate descriptions of each, they can easily be used in conjunction and often are.

What is encouraging from the research and reviews of psychological preparation for surgery is that they show that it is possible to intervene effectively using relatively uncomplicated procedures. Moreover, there is now sufficient information about their efficacy to be confident in recommending that they should be included as routine components of standard medical and nursing care for all patients undergoing surgery.

8.03.6 CONCLUSION

The outline of psychological preparations for surgery provides a very positive endpoint for this chapter. The development and success of these procedures not only constitute very concrete evidence of the importance and contribution of psychological factors in health care but also serves to link together some of the other main areas covered in this chapter. For example, the preparations can have important effects on the way in which postsurgical symptoms are interpreted and responded to by patients. Indeed, the efficacy of the interventions provides additional evidence of the role of self-regulatory processes and expectations in symptom perception since the provision of sensory information can provide the patient with a benign interpretation of predictable postsurgical symptoms. Moreover, it is clear that whatever specific mode of intervention is used, each of them involves aspects of communication between the HCP and the patient.

At the beginning of this chapter a brief mention was made of the variety of systems which have evolved for the delivery of health care in different countries. The psychological processes and topics covered here are of equal relevance across all these systems. It is notable that Johnston and Vogele (1993) end their meta-analysis with a similar observation since they find that psychological preparations for surgery have produced similar results in countries with both free market and public health-care provisions. The ubiquitous role of psychological processes in health care is a reflection of the relevance and the potential of research and practice in health psychology.

ACKNOWLEDGMENTS

I am particularly grateful to Susan Pybus for her help in producing this manuscript. Special thanks are also due to Rob Horne, Mary Rome, and Sue Williams for their contribution to specific parts of the chapter. Finally, thanks are also due to the editors for their encouragement, critical feedback, and patience.

8.04.1 INTRODUCTION

Most measurement issues in health psychology are similar to those in all other areas of psychology and are characterized by the problems of placing a metric on behavior and on mental states. Health psychology examines psychological and behavioral processes in health, illness, and health care and its measures are distinguished by the nature of the theoretical frameworks and questions addressed, by the diversity of measurement methods used, and by the context of the applications.

This introductory section deals with general measurement issues in health psychology. In the following sections, some of the measures used in the common areas of investigation are presented. We start with the assessment of healthy individuals, followed by measures used with people who are ill, then examine the measures adopted with both providers and users to investigate the process of health care and finally discuss measures that are used in all contexts.

8.04.1.1 Theoretical Frameworks and Questions Investigated

Health psychology measurement is undertaken in order to understand behavioral and psychological processes in health, illness, and health care. The purpose may be research or application, especially in the fields of public health or clinical medicine. Measures are used to address three main theoretically, based questions concerning:

(i) the assessment of psychological and behavioral indices of the status or amount of health, illness, or health care;

(ii) the assessment or evaluation of the psychological and behavioral consequences of health, illness, or health care;

(iii) the assessment of psychological and behavioral factors as predictors or explanations of health, illness, or health care.

In each case, the measurement of health, illness, and health care is essential.

Just as health is measured by psychological and behavioral processes, much of the assessment of illness and recovery from illness lies within this domain. Clinical signs and pathophysiological processes may be available in the assessment of patients with some conditions (such as respiratory function in chronic bronchitis, or immune function in AIDS). Frequently, however, the clinician assesses disease processes by ascertaining how the patients feel and what they are doing (as in rheumatoid arthritis or multiple sclerosis)—if patients are recovering well, they describe themselves as feeling better and doing more for themselves. Indeed, Kaplan (1990) has argued that these behavioral processes are the important outcome of illness and health care. Measurement of illness has therefore included assessment of the psychological and behavioral consequences of the disease processes.

Health care is largely a behavioral and interpersonal process. Indices of health care assess the use of services by patients, such as frequency of attendance at a clinic, as well as the performance of those involved in health care delivery (e.g., hand hygiene by surgical staff, provision of information by primary care physicians). These behavioral processes are likely to be a major influence on the effectiveness of health care as they determine the viability of delivery of biomedical treatments and advice. The behavior of patients in adhering to medical recommendations has long been recognized and methods of assessing adherence have been debated and developed, but the role of health professionals in determining patient outcomes has been less adequately assessed (Marteau & Johnston, 1991).

An important development in all industrialized countries has been the drive to develop evidence-based health care. Expansion of the need for medical care has resulted in financial pressures and the inevitable selectivity in the provision of care. It is clearly desirable to select those services which are both effective in achieving good health outcomes and efficient in their delivery, but this requires both evidence concerning which procedures or services are effective and efficient, and the successful implementation of these services. The assessment of effectiveness requires the measurement of health or health care outcomes, that is, scaling of the consequences of disease or health care. As indicated above, such measurement will frequently lie in a psychological or behavioral domain. Further, investigation of the implementation of interventions reveals that even those proven to be successful are not fully implemented; for example, appropriate thrombolysis for hospital patients has been shown to have the potential to reduce mortality, but there is evidence that it is not used appropriately in a large proportion of hospitals (Anderson et al., 1991). The assessment of health outcomes and the implementation of successful health care are key areas of health services research and are important areas of application for health psychology measures.

8.04.1.2 Measurement Approaches

As a result of the types of application, a wide range of measures is necessary. Health psychology investigations may include any of the following types of assessment to achieve measurement:

(i) interview (e.g., demographic information, self-report of behavior, beliefs, or feelings);

(ii) questionnaire, (e.g., standardized measures of individual differences such as optimism or coping);

(iii) observation of behavior (e.g., performance of self-care);

(iv) psychophysiology (e.g., cardiovascular reactivity to stressors);

(v) clinical indices (e.g., pulse rate, temperature, death);

(vi) pathophysiological indices (e.g., brain scan, blood cell counts);

(vii) information from health care records, (e.g., attendance at clinics, prescribed medication).

8.04.1.2.1 Interviews

Interviews or interviews incorporating questionnaires are the most common method of collecting data from people who are undergoing health care or who are ill. Interviews can help to standardize the presentation of the measurement materials in a way that could not be achieved in routine clinical assessments. They can also motivate and facilitate responses to long questionnaires, while at the same time being sensitive to fatigue, especially in people who are ill. Clearly, interview techniques can also be a source of error, if interviewers vary or if an interviewer's behavior is variable.

Interviews result in very diverse kinds of data. They may consist wholly or partially of closed precoded questions or they may contain open questions which require later coding. Some interviews may reproduce the format of a standardized interview, whereas others use newly designed questions. The most widely known example of a completely standardized interview in health psychology is the structured interview for the assessment of type A behavior (Friedman & Rosenman, 1964), where both the content and style of delivery of the questions is standardized as is the method of coding responses; both interviewers and coders require training and need to meet an acceptable standard of agreement with benchmark ratings. These ratings depend both on the content and style of response.

Open questions on interviews and questionnaires require subsequent work by the investigator in order to interpret the data and provide a basis for measurement. Some qualitative methods are used to explore new domains of investigation, by examining the predominant themes emerging from responses using a variety of techniques and theoretical frameworks (Michie, McDonald, & Marteau, 1996). These analyses can provide useful insights and may form a basis for the development of hypotheses or measures that can be satisfactorily validated. However, other methods are required if even the most basic level of measurement is to be achieved and this will be essential if evidence of the replicability of the methods and findings are desired. The minimal level of measurement enables the investigator to classify a response as belonging to a specified category or not. For example, in interviews with patients with motor neurone disease, a question about who was with them when they were told was reliably categorized as "told alone" or "with someone present" (Johnston, Earel, Mitchell, Morrison, & Wright, 1996). Without at least nominal or categorical measurement, it is impossible to establish the reliability, validity, frequency, associations, consequences, or causal status of the phenomena investigated.

Normally, investigators develop a coding frame from preliminary work with a subset of the data or from a preexisting theoretically or empirically-based framework. For example, the CAVE (Peterson, Buchanan, & Seligman, 1995) codes spontaneous utterances in terms of the attributions presented and classifies the material in terms of the respondent's explanatory style, whereas LIWC (Pennebaker, Mayne, & Francis, 1997) is a computer program that searches for key words reflecting the individual's attempts to find meaning. A group of four papers using different coding frames to analyze the same interview material (Folkman, 1997; Nolen-Hoeksema, McBride, & Larson, 1997; Pennebaker et al., 1997; Stein, Folkman, Trabasso, & Richards 1997) illustrates the diversity of measurement approaches that can be applied to spontaneous responses to open questions. This kind of coding frame guides the allocation of a code, usually a numerical code, to the responses. It is then possible to examine the reliability of the coding by comparing coders or the same coder on different occasions or on different parts of the data. Reliable data can then be investigated using appropriate statistical methods to examine the research questions (see Volume 3 of this series).

Where interview responses take a precoded closed format, then coding responses is not an issue. Scoring and measurement then depend on the same psychometric issues as apply to questionnaires.

8.04.1.2.2 Questionnaires

Questionnaires are widely used in health psychology to assess beliefs, attitudes, knowledge, mood, indices of individual differences, experience of health care, health-related behaviors, adherence to medical advice, etc. We have described or evaluated over 50 such measures in a user's portfolio of health psychology measures which provides a fuller account of the measures and their use (Johnston, Wright, & Weinman, 1995).

Such easily accessible measures can appear to the novice health psychology investigator as an attractive display of off-the-shelf techniques that can solve many of the problems in research design. However, there are a number of pitfalls. First, the measures vary in the quality of their psychometric properties. There are measures that have insufficient items to achieve satisfactory reliability and, for some, reliability may not even have been assessed. Some form of internal consistency should be available and, where appropriate, evidence of test–retest and interrater reliability should be provided. Measures should also have demonstrated validity. Validity is normally conceptualized within a theoretical framework that defines the content and the functioning of the construct being measured. A second pitfall for the naive researcher is the use of measures outside the theoretical framework of their development and validity. It can be perplexing when a series of quite different measures all seem to be relevant to the same domain, but this can often be explained in terms of the underlying theoretical framework. For example, many measures assess control cognitions; however, some of these are directly associated with Rotter's (1966) Social Learning Theory, others are related to Bandura's (1977, 1997) Social Cognitive Model, and others arise from Attribution Theory (Weiner, 1986). The investigator should ensure that the measures chosen are compatible with the theory guiding the research. A third pitfall lies in the use of measures with populations they were not designed for. For example, it may be tempting to use a test validated with adults in work with children or to use assessments shown to be valid with ill people in a study of a healthy community-based sample. Clearly it is important that measures are acceptable and applicable with the population being investigated.

There are even greater hurdles in designing new measures that have no previous development, evaluation, or normative data, but this may prove necessary for the exploration of new constructs, theoretical approaches, or applications. It is helpful if the theoretical formulation guides the development of measures as was done for the Theory of Reasoned Action (Fishbein & Azjen, 1975). However, the content and format of new questionnaires is likely to begin with pilot or exploratory work, often using qualitative methods of data collection (see Volume 3 of this series) to identify salient material. For example, in developing a measure of perceived control of recovery from disabling disease, we started with spontaneous comments by patients which were subsequently evaluated using standard reliability analyses and tested for construct validity (Partridge & Johnston, 1989).

The problems in using self-report interview or questionnaire data are widely recognized. Various response sets may affect responses and in health psychology, social desirability (the tendency to give responses attracting the approval of others) and negative affectivity (bias towards a negative view of self, circumstances, and events) may be particularly important. Social desirability is likely to be important where there are recommended or expected styles of behavior. For example, social desirability might lead to exaggeration of adherence to medical advice or health protective behaviors, but might result in under-reporting of health-damaging behaviors such as smoking. It is often valuable to assess and make allowance for social desirability by using an instrument such as the Marlowe–Crown Inventory as in Weinberger, Scwartz, and Davidson (1979). Watson and Pennebaker (1989) suggest that negative affectivity may be a source of error in examining the relationship between self-report measures where each measure may be influenced by the individual's tendency to focus on the negative aspect; for example, correlations between mood and health status might simply be due to individual differences in negative affectivity coloring perceptions of health status.

Although such considerations apply to all measures, they may prove particularly important where measures involve self-report. These measures are commonly used in health psychology and the sources of error in self-report measures are generally recognized (Abrahams & Hampson, 1996; Haaga, 1997). However, they may be a particularly serious source of bias if the investigator examines the relationship between two such measures. If both measures are subject to the same form of response set, such as social desirability or negative affectivity, then apparent relationships between constructs might be due entirely to the correlation in the biases in the measures.

8.04.1.2.3 Observation of behavior

Observations of behavior may be undertaken where self-report is impossible, or to supplement self-report measures. These observations may be made by health professionals, such as the clinical assessments frequently used in studies of preparation for surgery (Anderson, 1987), by members of the target person's household as in studies of smoking, or by the investigators as in the observation of limitations in the performance of daily activities following illness.

Such observations are limited by the observers' inability to see the full range of the behavior. Most health professionals will see the patient for quite short periods, and even nursing staff are typically limited to 8 or 12 hours per day. Lack of concordance between self-report and the observation of the professional may therefore be due to limitations in their observations as well as the noted problems in self-report. Nurses assess surgical patients as having more emotional problems than the patients report and are less accurate at pinpointing patients' emotional problems than other patients are (Johnston, 1982), perhaps because of the limited interactions they have with patients. Different health professionals perform different tasks and have very different styles of interaction with patients and this may result in systematic, rather than just random, variations in the assessments they make (M. Johnston et al., 1987). Thus, the choice of observer may critically affect the results obtained.

Members of the individual's household or social network may also be limited in the observations they can make. Very often they are involved in assessing the performance of undesirable, health-damaging behaviors such as smoking or consumption of fatty food, or adherence to a recommended medication, diet, or exercise regimen. The chosen observer may be unable to ascertain whether the person has participated in the target behavior when out of sight, or may be motivated to present a favorable picture of the friend or relative they are observing.

When investigators observe behavior, this is always restricted either in time or in the range of behaviors. For example, assessments of limitations of function typically require the performance of the activity, often in clinical rather than home settings. Thus, while observational methods are attractive as an adjunct to self-report methods used in interviews and questionnaires, they too have practical constraints, sources of unreliability, and factors which limit their validity.

8.04.1.2.4 Psychophysiological measurement

Many psychological processes implicated in the etiology, treatment, and assessment of disease and disease-related processes involve changes in physiological systems in response to psychological stimuli. This is particularly the case if stress, stress reduction, or emotion is involved. The measures used in particular investigations will often reflect the disease under study so, for example, heart rate and blood pressure are used in studies of heart disease (see Chapter 8.08, this volume), gastric measures in studies of gastrointestinal disorders (see Chapter 8.12, this volume), and measures of muscular tension in studies of headache (see Chapter 8.23, this volume). A general review of psychophysiological processes in disease is provided by Steptoe (Chapter 8.02, this volume).

(i) Stress testing

The actual use made of psychophysiological techniques obviously depends on the question under investigation. However, many studies involve contrasting a period when the subject is relaxed with when they are stressed. The choice of condition for both periods can be critical. Few subjects find the psychophysiological laboratory immediately relaxing and it may be difficult to control and standardize the temperature, humidity, and sound level. The choice of stressor and control tasks is also critical. The challenging video game that produces an enormous elevation in heart rate (HR) and systolic blood pressure (SBP) in a male teenager may be totally inappropriate in a late-middle-aged patient with heart disease where carefully selected role-play may be a more useful task (Ironson et al., 1992). It can also be difficult to find control tasks with similar metabolic requirements to the stressors to ensure that differences due to physical effort are not interpreted as being due to psychological stress.

(ii) Physiological measures

Some of the most commonly used psychophysiological measures are outlined below. Cacioppo and Tassiary (1990) describe most aspects of psychophysiological measurement in their excellent *Principles of psychophysiology*. The main bodily systems that are studied in health psychology using psychophysiological methods are the cardiovascular system, the respiratory system, aspects of sweating, the gastrointestinal system, and the skeletomuscular system. Hormonal measures such as adrenaline, noradrenaline, and cortisol are also often taken, as are a wide variety of measures of immune function.

(a) Cardiovascular. Cardiovascular measures are among the most widely used psychophysiological measures. This is because of their use in the study of the stress process and also because of the specific relationship between such responses and cardiovascular disease (see Chapters 8.02 and 8.08, this volume). Heart rate, the most common cardiovascular measure, is reliably recorded from the electrocardiogram (ECG), a record of the electrical activity of the heart.

There may be both intra- and interassessor unreliability in the manual assessment of blood pressure and therefore automatic assessments are better for most purposes. Blood pressure (BP) is determined by the amount of blood pumped by the heart (cardiac output) and the resistance of the blood vessels to the passage of blood (peripheral resistance). On each cardiac cycle, pressure fluctuates between a maximum value as the blood is ejected (SBP) and a minimal value just before the next heart beat (diastolic blood pressure, DBP). BP is measured in millimeters of mercury (mmHg). In healthy individuals the SBP is approximately 120 mmHg, and the DBP is 80 mmHg. BP can rise markedly during psychological stress and raised BP at rest defines hypertension.

The more specialist measures of cardiac output and peripheral blood flow are less commonly used. As there are considerable technical challenges in the direct measurement of cardiac output, the most common measurement approaches are indirect, and based on measuring changes in electrical impedance across the heart. Peripheral resistance cannot be determined directly, but can be calculated from BP and cardiac output. However, flow in specific parts of the vascular system can be measured. The most widely used method is photoelectric plethysmography, which relies on the fact that red blood cells scatter infrared light. When infrared light is passed through the skin or scattered by the blood in skin, variations in light between the light source and a detector can give an indication of blood flow. Such methods are used in some heart-rate detectors that do not use the ECG, and have been used in the study of abnormalities of blood flow in the temporal artery in headache (see Chapter 8.23, this volume). More demanding methods, based on direct measures of limb volume, can provide quantitative measures of peripheral blood flow. Freedman (1989) provides an application in Raynaud's disease. Further details on cardiovascular measurement can be found in Steptoe and Johnston (1991).

(b) Respiration. Respiration is studied in its own right in conditions with respiratory symptoms and also because variations in breathing have a profound effect on other bodily systems such as the cardiovascular system. Respiration rate can be determined from either belt-like devices round the chest that produce a electrical signal that varies with chest expansion or from thermistors placed near a nostril, used to detect the difference in temperature between inhaled and exhaled air. Other measures to indicate different types of breathing, such as in hyperventilation, require the use of several chest-movement detectors.

(c) Sweating. Sweating-related activity is a widely used psychophysiological measure. The number of sweat glands open determines variations in the resistance of the body to the passage of a small electric current between two sites. In certain areas of the skin, such as the fingertips, the main cause of sweating is arousal (rather than temperature), and therefore variations in electrodermal measures such as skin conductance provide a very useful measure of arousal. Since sweating is under purely sympathetic control, skin conductance is more readily interpreted than other measures, such as HR, which reflect the balance between the sympathetic and parasympathetic systems.

(d) Gastrointestinal. The gastrointestinal system is measured using the electrogastrogram, a record of the electrical signals associated with contractions of the gut.

(e) Musculoskeletal. Activity in the musculoskeletal system is recorded using the electromyogram, a record of the electrical impulses produced by contracting muscle fibers. This can give information on small specific muscles, such as the frontalis muscle often studied in relation to headache (see Chapter 8.23, this volume), or larger muscles relating to gross bodily movements (see Chapter 8.19, this volume).

(f) Stress hormones. The stress hormones epinephrine, norepinephrine, and cortisol can be measured in either blood, urine, or saliva. Although these measures can be illuminating, the assays involved and their interpretation is a complex matter. Difficulties can arise in the methods of collection of samples, in the storage prior to assay, and in the reliability of assays over laboratories, technicians, and time.

(g) Immune measures. The use of immunological measures, such as various types of immunoglobulin or T lymphocytes, is highly attractive in some areas of research such as infection, cancer, or HIV (see Chapters 8.10 and

8.23, this volume). These measures incur the same hazards as stress hormone assays but, additionally, this is a rapidly advancing field and the choice and interpretation of measures requires current, specialist expertise.

8.04.1.2.5 Clinical and pathophysiological indices

Medicine uses many clinical and pathophysiogical indices in screening populations, investigating disease, and charting recovery. These measures include: routine clinical measures such as temperature or pulse rate; indices of heart disease derived from the ECG or echocardiogram; measures of bacterial infection determined from samples of bodily fluids; the simple imaging techniques like the X-ray that have been in use for decades; and complex imaging of the functioning body now possible with techniques such as magnetic resonance imaging (MRI). In health psychology, one may wish to understand such measures either to have a better understanding of the medical condition of a patient in treatment or to use the measures in research. In either case it is important to ask oneself if the information is really necessary. Many psychologists enter this field with the belief that medicine has established valid and reliable measures of illness and recovery. This is not always so. Much of medicine relies on the patient's report of their symptoms. In many instances, treatments are given and terminated and patients are discharged from hospital when they indicate that they are better by their speech or actions. Other sections of this chapter indicate how such symptoms can be measured with much greater reliability and precision than is common in the medical assessment of symptoms.

If one is treating a patient with a condition like diabetes, hypertension, or asthma, one often wishes to know the severity of the condition, the prognosis, or the patient's medical progress. Information on blood sugar, BP, or peak respiratory flow may inform treatment or, at the very least, increase communication and rapport between psychologist and client. A considerable amount of such information is provided in the chapters of this volume on specific medical conditions. In addition, it is likely that one of the current editions of standard large medical textbooks designed for undergraduate use will provide more than enough information. Difficulties can arise if textbooks use language that is not appropriate to local or national diagnostic and treatment approaches, and locally available patient pamphlets may be equally valuable.

If medical test data is needed for research purposes, then the usual concerns over measurement standards apply. It is unwise to assume that medical measurement is either reliable or valid; for example, we have found that repeated measures of height in adults may not achieve high reliability. In overstretched medical environments, clinical testing is often carried out under far from ideal conditions. For example, sphygmomanometers (for measuring blood pressure) are often not serviced or even checked for long periods, and standard conditions for the taking of blood or urine samples are not always observed. The information obtained from such tests may be adequate for clinical purposes, such as preliminary screening or monitoring change, but not for research where accurate absolute values are required. It is therefore incumbent on the researcher to ensure that the measures they are using in research are of research quality, with known reliability and validity, and adequate to answer the research questions.

8.04.1.2.6 Health-care records

Health-care records may be used as sources of data on the behavior of a patient, such as in seeking health-care, the nature of medical recommendations or treatment, the results of clinical assessments, or the patient's health or illness status. As these data were typically not recorded for the purposes that the health psychology investigator has in mind, they are unlikely to be biased with respect to the question investigated. However, they may have other biases and sources of error, and are frequently incomplete and therefore an unreliable source of information. As a result, they are normally used to back up or validate other, more direct, methods, rather than as the main source of evidence.

8.04.1.3 Design of Investigations

Measurement can be improved if some thought is given to the selection and timing of measures, as well as to the measurement implications of the overall design of the investigation in the planning stage.

Investigators often use a series of measures, especially questionnaires, and then the order of presentation needs to be considered. If a measure of transitory state, such as anxiety or pain, is included, this should normally be presented first as otherwise the responses may be largely determined by the effects of completing the questionnaires. For example, if respondents are required to answer questions about their illness and its future management first, this might increase the level of anxiety reported.

Indeed, experimental approaches to mood manipulation may ask participants to recall just such events with reliable effects on mood (Fisher & Johnston, 1996a). There may still be order effects for other measures and some investigators present questionnaires in a randomized or counterbalanced order to ensure that results obtained are not simply due to order of presentation. Although this is desirable scientifically, it may sometimes reduce the acceptability to respondents if, for example, a clinical research interview does not appear to follow a logical sequence. Some error may be reduced if measures are not all completed at the same time. For example, mood might be measured on a different occasion from recall of illness events.

If a causal analysis is required, then a longitudinal design will be more effective than a cross-sectional design where it is not even possible to assert that the causal construct was assessed prior to the consequence. Experimental designs are even more effective and these may range from short-term laboratory manipulations to randomized controlled trials of therapeutic interventions. For example, the effect of perceived control on disability was examined experimentally in the laboratory by manipulating control cognitions and observing the subsequent functional limitations (Fisher & Johnston, 1996b). An example of the use of a randomized trial in investing causal explanations is provided in the recurrent coronary prevention project (Friedman et al., 1986) where cognitive-behavioral methods were used to reduce Type A behavior in the experimental group but not in the control group; finding a reduced rate of recurrent cardiac episodes in the experimental group furthered the hypothesis that Type A behavior caused coronary heart disease (CHD). Other designs have been developed specifically for research in clinical situations (see Chapter 8.05, this volume).

8.04.2 MEASURES USED WITH HEALTHY PEOPLE

This section addresses measures used in studying people who have not been selected as being ill or in need of medical care. Typically these are populations of students or community residents and may well contain many people who are ill and may even be receiving care.

Undoubtedly the two main theoretical questions addressed in these populations have been the understanding of factors influencing health-related behaviors, namely behaviors likely to affect health (see Chapter 8.01, this volume), and identifying psychological and behavioral characteristics predictive of disease, especially heart disease and cancer. A fundamental question that is sometimes addressed explicitly is how to measure health.

8.04.2.1 Measuring Health

It has proved extremely difficult to measure health (Bowling, 1991). This is hardly surprising given the lack of an agreed definition of health. The complex WHO (World Health Organisation) definition of health that is commonly adopted includes social, psychological, and physical aspects (Abelin, Brzezinski, & Carstairs, 1987). There is common agreement that health is more than the absence of illness and that it is characterized by the individual's vitality and functional capacity, their mood and outlook, and their participation in activities. Wright (1990) has conceptualized health as three dimensional: freedom from unpleasant symptoms and sensations; ability to perform conventional roles and duties; and possession of physiological, psychological, and social resources.

Assessment of absence of symptoms as an index of health has proved problematic as people who would be characterized as healthy are unlikely to be symptom-free. Even number of symptoms proves problematic, as symptom reporting is associated with mood, emotional disorder, and negative affectivity. For example, many measures of emotional disorder such as the GHQ (Goldberg & Williams, 1988) ask about the experience of somatic symptoms and have found that people with greater emotional disorder report more somatic symptoms. In a similar vein, use of health services may reflect individual patterns of responding to symptoms, rather than indexing health *per se*. Watson and Pennebaker (1989) suggest that there are individual differences in negative affectivity, the tendency to attend to and report negative experiences including sensations which might be interpreted as symptoms. They have developed a measure, the PILL, which assesses the tendency to endorse symptoms that can be used to allow for negative affectivity. Thus measures of symptoms or health-care usage may be misleading as an index of "health."

Simple self-report measures of health, such as ratings on four-point verbal rating scales from excellent to poor, have been found to be predictive of future mortality (Idler, 1992). Even when allowance is made for concurrent illness, people rating their health as poor are more likely to be dead at follow-up than those giving higher ratings. These results suggest that such ratings must have some validity as measures of health. Their main limitation is the lack of sensitivity inherent in such brief scales.

Measures of general well-being such as the Bradburn Affect Balance Scale (Bradburn, 1969) or even measures of satisfaction with life (Diener, Emmons, Larson, & Griffin, 1985) may come closer to the WHO concept of health as they allow the individual to evaluate all aspects of functioning. It is curious to note that the measurement of health-related quality of life has mainly been investigated in ill, rather than healthy, populations as discussed below. These measures are rarely evaluated with healthy populations and are therefore likely to be relatively insensitive to variations in their health.

Health may also be characterized as an expectation of continuing absence of illness, either due to engagement in health-protective behaviors such as taking exercise, or to having few risk factors for disease. Risk factors may be genetic (e.g., heart disease or diabetes), physiological (e.g., high blood pressure), or environmental (e.g., living in an area of high air pollution). However, many risk factors are behavioral, such as smoking or diet, and these may be assessed along with health-protective behaviors as part of the measurement of health.

8.04.2.2 Health-related Behavior

Two kinds of health-related behaviors can be identified. The first group of behaviors are those that have been demonstrated to confer health risk or disease protection. Evidence from the Alameda County study (Schoenborn, 1993) and from other epidemiological studies demonstrates that some behaviors, especially smoking (Doll, Peto, Wheatley, Gray, & Sutherland, 1994), increase risk, while others, such as engaging in exercise, appear protective. Clinical and public health interventions are frequently directed at changing behavior to reduce risk and enhance protective behaviors (Oxcheck Study Group, 1994; Family Heart Study Group, 1994; see Chapter 8.29, this volume). The behavioral assessments found to predict disease end-points in epidemiological studies have demonstrated predictive validity and should be used in order to assess risk in a population. For example, comparison with risk data from the British Regional Heart Study (Shaper et al., 1982; Shaper, Pocock, Phillips, & Wacker, 1987) is only valid if questioning about smoking and diet follow the methods used in that study.

The other group of behaviors are the health behaviors, defined as those behaviors that people undertake in the belief that they will prevent disease or ensure detection prior to symptoms (Kasl & Cobb, 1966). There is ample evidence that most people report engaging in a number of these behaviors (Amir, 1987; Cox et al., 1987; Harris & Guten, 1979). Several checklists of these behaviors have been published (Amir, 1987; Prochaska, Leventhal, Leventhal, & Keller, 1985), but unlike the risk/protective behaviors that can be validated against epidemiological findings, there is little evidence of validation of these checklists. Self-reports of behavior are likely to be subject to bias, especially social desirability bias, as discussed above. Until they are validated against some other measure of health behaviors, their value as assessments of health behaviors is restricted and their primary value is in assessing the rate of reporting behaviors.

8.04.2.3 Health Cognitions

A major group of theoretical models have been developed to predict health-related behaviours from health-relevant social cognitions (see Chapter 8.01, this volume; Conner & Norman, 1996). Models such as the Health Belief Model, Social Cognitive Theory, and the Theory of Planned Behavior propose that a range of health and health-behavior cognitions determine health-relevant behaviors. Health cognitions include outcome expectancy, perceived severity, perceived vulnerability, health locus of control, and health value, whereas health-behavior-relevant cognitions include response efficacy, self-efficacy, behavioral intention, implementation intention, and action plans.

These models raise some important measurement issues: the individual may not be aware of the cognitive processes influencing behavior; it may be difficult to operationalize all of the model's constructs; and the problems with self-report measures have been noted. Further, the models vary in the precision of specification of measurement of core constructs, ranging from the proscriptive Theory of Planned Behavior to the very poorly defined constructs of the Health Belief Model. Some constructs have standardised measures that have psychometric validation and published norms. The best known of these is the Multidimensional Health Locus of Control (MHLC) scale (Wallston, Wallston, & Devellis, 1978), which assess three components: internal, powerful others, and chance locus of control.

Although this measure has been criticized for its lack of specific relevance for people who are ill, it continues to be appropriate for healthy populations. Wallston (1992) has proposed that locus of control by itself should not be enough to predict health behavior and proposed that it should be combined with a new construct, perceived health competence, a construct akin to generalized health self-efficacy (Smith, Wallston, & Smith 1995). The social learning theory, from which locus of control derived, would suggest that the MHLC should only predict health behavior in combination with a measure of health value (Lau, Hartman, & Ware, 1986) and there has been criticism of investigations in this area for using the model inappropriately.

This relates to a more general methodological problem in this area of investigation—the selection of variables from models without addressing complete models. The investigator needs to have a clear objective. If the intention is simply to explain as much behavior as possible, then the investigator is justified in choosing the most likely combination of variables from whichever models seem appropriate. If the objective is to test a model, then all the constructs of the model, and none from other models, should be assessed. If the aim is to test the power of the model to explain behavior, then only the proximal determinants specified by the model need to be investigated; so, for example, in the Theory of Planned Behavior (see Chapter 8.01, this volume), only behavioral intention and perceived behavioral control would need to be assessed as all other variables act through these two.

8.04.2.4 Predicting Disease

The main issues of measurement in predicting disease from individual differences in behavior are:

(i) the specificity of the hypothesized link between behavior and disease, because this affects the choice of behavioral measure and disease endpoint;

(ii) the stability of the behavior over time or environment;

(iii) the independence of initial health status and the predictor measure;

(iv) the independent measurement of predictor and endpoint;

(v) the costs and practicality of the measures.

8.04.2.4.1 Hypothesized link between behavior and disease

For much of the twentieth century there have been two competing views on the psychological factors thought to predict disease. One camp, which was most clearly manifest in the writings of the psychoanalytically influenced psychosomaticists of the 1930s and 1940s, held that there was a very specific relationship between particular personality types and specific diseases. The alternative view, exemplified by the theories of Cannon and Selye, maintained that disease was the result of general stress-related processes. More sophisticated versions of the same positions can be seen today (see Chapter 8.02, this volume) and lead to very different measures. Type A, or coronary prone, behavior (Friedman & Rosenman, 1964), and the more recent emphasis on hostility (Hecker, Chesney, Black, & Frautschi, 1988), or even type of hostility (Siegman, Dembroski, & Ringel, 1987), is a good example of a specific personality/disease theory. Friedman and Booth-Kewley's (1987) concept of the disease-prone personality is a version of a very general theory, as is Seligman's theory of a pessimistic explanatory style (Peterson et al., 1985).

Friedman and Rosenman (1964) described Type A behavior (TAB) as a pattern of competitive, time-pressured, and aggressive behavior that led to CHD and developed a specific structured interview to assess it. They held that TAB was best measured by an observing behavior (during the interview) and not by questionnaire. In the landmark Western Collaborative Group study (WCGS), they showed that, in accord with their theory, TAB predicted a specific endpoint, CHD, independently of the classical risk factors for heart disease (Rosenman et al., 1975). Friedman and Rosenman's emphasis on specificity was extended by later researchers who showed the concept of TAB was too broad and that hostility (Hecker et al., 1988) or perhaps even a specific type of expressive hostility (Siegman et al., 1987) was the main psychological predictor of CHD. In marked contrast, Friedman and Booth-Kewley (1987) hypothesize that there is a general tendency to experience negative emotions which leads to enhanced risk of disease of many kinds. They are able to summarize an extensive literature describing many different negative psychological states, such as anxiety, depression, or anger, and relate them to many different diseases, such as CHD, asthma, or cancer. These two types of theory lead to markedly different measurement concerns with one requiring very specific behavioral measures, whereas the other is best served by very broad measures of negative emotion. Similarly, one theory requires careful measurement of a specific endpoint, CHD, whereas the other requires measures of all causes of morbidity or even total mortality.

8.04.2.4.2 Stability of behavior

Typically, theories in this field imply that an enduring trait or style exacerbates psychophysiological processes which result in disease.

Thus, both the predictive measure and the underlying trait being measured have to be stable over the prolonged time periods likely to be necessary for disease to develop. This may be plausible for the personality characteristics described by Friedman and Booth-Kewley, but is less certain for TAB. Friedman and Rosenman held that TAB was a product of the subject's environment and would change if the environment changed. It is the case that TAB in the WCGS was predictive of CHD at 8.5 years postmeasurement (Rosenman et al., 1975) but not at 22 years (Ragland & Brand, 1988) and there are some indications that most of the predictive power of TAB falls in the first few years after assessment. There are predictors that are thought to be specifically short term such as vital exhaustion that predicts myocardial infarction best in the year or two after assessment (Appels & Otten, 1992).

8.04.2.4.3 Independence of initial health status and predictor behavior

Predictive studies are seriously compromised if the subjects' current health status affects the predictive measure. So, for example, early reports of perceived heath predicting mortality in the Alameda County study might have been due to perceived health being affected by concurrent disease, but this is unlikely to be the explanation of prediction over decades (Schoenborn, 1993). This problem of health status affecting the predictor is rare in studies of healthy subjects, especially if care is taken to screen for disease. However, it is an obvious concern when subjects are selected for early signs of disease, as in the studies of vital exhaustion (Appels & Otten, 1992). The problem usually occurs when studying a short-term predictor of a comparatively rare event, such as a myocardial infarction; a convenient way of ensuring enough events in a short time is to select high-risk subjects but then their state of health may affect psychological predictors such as depression or exhaustion. The best solution is to test a substantial number of unselected subjects so that enough events occur in the critical time period.

8.04.2.4.4 Independence of predictor behavior and disease endpoint

In most predictive studies predictor and endpoint are, in measurement terms, independent, that is, the disease endpoint is determined without knowledge of the predictor. However, when self-report is used to define the predictor and the endpoint there is a real possibility of the relationship being inflated through common method variance. This is serious problem when concepts such as the disease-prone personality are used to predict conditions which depend on the patient's report of symptoms (e.g., angina pectoris), particularly as the disease-prone personality has an obvious similarity with Watson and Pennebaker's (1989) concept of negative affectivity which affects symptom reporting.

8.04.2.4.5 Costs and practicality of measures

Predictive studies often involve the testing and follow-up of many subjects. Such studies are expensive, are often multidisciplinary, and there is a great pressure to measure as many predictive factors as possible with minimal load on the respondents. As a result, the epidemiological literature is replete with studies in which inadequate psychological measures fail to predict disease. A striking example was the decision, understandable but probably unfortunate, of many researchers to replace Friedman and Rosenman's (1964) expensive and time-consuming TAB structured interview with much simpler inexpensive questionnaires (D. W. Johnston et al., 1987). It has been known for some time that, although different questionnaire measures of TAB correlate satisfactorily (Johnston & Shaper, 1983), they do not measure the same behaviors as the structured interview (Matthews, Krantz, Dembroski, & MacDougall, 1982) and that aspects of TAB which relate to CHD may not be assessed well by questionnaire. Adequate psychological measurement is necessary in predictive studies since the cost of a longitudinal study that fails through poor measurement is immense.

8.04.3 MEASURES USED WITH ILL PEOPLE

Under this heading, measures are considered which have been used with individuals identified by their illness status although they may not be concurrently experiencing illness. In addition to their relevance for ill people, such measures share a sensitivity to the respondent's status, for example, by being limited in length.

The central issues here are to measure how ill the person is, what the effects of illness are and how individuals respond to and cope with illness. (The word "illness" is used to refer to the subjective experience associated with disease processes as we believe it has universal meaning. In American English, the word "sickness" would be synonymous, but in other parts of the world this term is confined to illness associated with nausea.)

8.04.3.1 Measuring Illness

It can be a source of some confusion and frustration to discover that there are no biomedical indices of illness. Although the state seems subjectively recognizable and can be meaningfully replicated in animal studies, there is as yet no measure which reflects it. Recent animal research suggests that the state of illness may be associated with raised brain cytokines (Dantzer, 1997), but even this research offers little immediate prospect of a useful biomedical measure. The concept of illness, the subjective experience, is contrasted with the concept of disease, the pathophysiological process. For some diseases, it is possible to obtain a biomedical measure of the disease process such as degree of atherosclerotic occlusion in cardiovascular disease, degree of invasion of cancer cells, or loss of CD4 cells in AIDS. For others such as rheumatoid arthritis, there are indices of current inflammatory activity. However, patient "illness" may not relate directly to the disease process and, for many conditions, the main clinical and research assessments depend on patient observation or self-report. So, instead of reliable biomedical indices, "illness" is characterized by the subjective experience and associated behaviors.

The problem of measuring illness and disease is illustrated by Bowling (1995) in her book *Measuring disease*. She includes measures of symptoms, pain, emotional states, disability, and quality of life. However, none of these measures disease as such and each is influenced by psychological and/or social processes in addition to disease processes. As noted, the experience and report of symptoms may be influenced by individual differences in negative affectivity, but will also be affected by current attention, mood, cognitive, and social factors. As the behavioral, emotional, and quality of life consequences of disease are likely to be influenced by different factors, they are each considered separately.

8.04.3.1.1 Symptoms and pain

Problems in assessing the subjective experience of symptoms have been discussed above for healthy populations. Thus symptom checklists (Dunnell & Cartwright, 1972) need to be used with caution. In ill populations, there are disease-specific measures of symptoms such as measures included within composite measures. Examples, are the Rotterdam Symptom Checklist for cancer (de Haes, Van Knippenberg, & Neijt, 1990) or the Arthritis Impact Measurement Scale (Meenan, Gertman, & Mason, 1980). Such measures tend to have good internal consistency and have been validated using factor analytic methods and concurrent and predictive validation against other clinical or functional measures.

Pain is an important symptom of many conditions and an important motivator in seeking health care. Like other symptoms it is a subjective experience and therefore difficult to assess and validate measurement. The best known and most widely used measure is the McGill Pain Questionnaire (MPQ) (Melsack, 1975) which allows separate evaluation of sensory, affective, and evaluative components of pain. It records location, change with time, and factors influencing the pain and provides three main measures of intensity, the number of words chosen, the pain rating index, and the present pain intensity rating. A short form of the MPQ has been introduced which correlates well with the full MPQ and demonstrates sensitivity to change (Melsack, 1987). In clinical settings where, due to pain, patients may not have the concentration required for more extensive measures, a variety of single-item numerical and verbal pain rating scales have been used (see Chapter 8.24, this volume).

8.04.3.1.2 Behavioral consequences of disease

The WHO analysis of the consequences of disease identified three consequences: impairment or loss of structure/function, disability or loss of performance of activities, and handicap or loss of social roles (WHO, 1980). It was proposed that disability resulted from impairment and that handicap resulted from both impairment and disability. Although there has been much debate about this analysis, other (e.g. Nagi, 1991) and more recent WHO (1997) approaches retain the main characterizations of the elements involved.

Disability is defined in terms of behavior (Johnston, 1996) and is measured in terms of behavioral performance or capability. Thus, general disability measures assess limitations in the performance of normal functions; for example, the Barthel Index (Mahoney & Barthel, 1965) includes walking, bladder control, dressing, and using stairs, whereas more specific measures of Activities of Daily Living (ADL) assess the performance of everyday tasks such as self-care, shopping, and household tasks (Katz, Ford, Moskowitz, Jackson, & Jaffe, 1963; Lincoln & Edmans, 1990).

There is debate about whether measures should assess what the individual does or what they can do. Clearly, limitation in capacity is the construct most closely related to the direct consequence of disease, whereas limitation in performance may indicate the additional psychological, social, and environmental influences. Similar issues arise in other areas of performance psychology, where techniques such as dual-task performance have evolved to assess capacity; using the argument that, although performance may be maintained despite lower capability, the extra effort involved is assessed by examining the effects on a second task. To date, measures of disability have not taken account of this problem, and dual-task measures may enhance the measures in this field.

The behavioral consequences of disease may not simply be loss of activities, but may also involve the performance of new activities. The observable behaviors associated with pain have been assessed and they include additional behavior as well as loss of activities. Keefe and Block (1982) and Richards, Nepomuceno, Riles, and Su (1982) have developed measures of pain behaviors (e.g., grimacing, guarding movements, rubbing) which are assessed by observers. These measures are not necessarily closely related to self-report pain measures and may additionally reflect the individual's response to pain experience.

8.04.3.1.3 Emotional consequences of disease

Illness in oneself or in close family or friends is recognized as a significant source of stress in most methods of assessing life events and difficulties, including the original Social Readjustment Rating Scale (Holmes & Rahe, 1967). The emotional consequences can be assessed using any of the available measures of mood such as the STAI (Spielberger, 1983), the profile of Mood States (McNair, Lorr, & Droppelman, 1992) the CES-D (Radloff, 1977), or the GHQ (Goldberg & William, 1988). However, these can be confounding where somatic symptoms may be interpreted as emotional symptoms, such as where loss of appetite or slowing are indices of depression. Zigmond and Snaith (1983) introduced the Hospital Anxiety and Depression Scale (HADS) which they suggested minimized such confounding by reducing the number of such items. However, the success of this scale compared with other scales has not been assessed and, because it contains items such as "I feel as if I am slowed down," it may still contain contaminated items.

This problem does not arise in assessing the emotional consequences for people close to the patient and there is ample evidence that the emotional consequences may be as great for them as for the patient, for example, following myocardial infarction (MI). Where they are also caregivers, measures of caregiver burden are a combination of the emotional and behavioral burdens of caregivers (Orbell, 1996). The stress is observed not only in self-report measures but also in evidence of impaired immune function (Kennedy, Kiecolt-Glaser, & Glaser, 1988) with resulting vulnerability to disease. Some measures such as the GAIS and PAIS (Derogatis, 1975, 1986) assess adjustment to illness. Adjustment is frequently addressed as a form of coping or as illness cognitions (see Sections 8.04.3.2 and 8.04.3.3).

8.04.3.1.4 Quality of life

Although the construct of quality of life (QL) is widely used in assessing the consequences of disease, there are quite divergent schools of thought regarding definition and measurement. On the one hand, it is argued that the measures should assess the quality objectively, while on the other it is proposed that QL can only be evaluated according to the individual's expectations and values. Measures such as the Quality Adjusted Life Year (QALY) (Kind & Rosser, 1988; Rosser & Kind, 1978) or the SF-36 (Jenkinson, Coulter, & Loright, 1993) assume a universal value system, and so by assessing the individual's limitations it is possible to give an overall value to QL. By contrast, the Patient Generated Index (PGI) (Ruta, Garratt, Leng, Russell, & MacDonald, 1994) and the SEIQOL (O'Boyle, McGee, & Joyce, 1994) assess the individual's value system as well as the current levels of achievement in valued areas. The values are combined with the levels of achievement to generate an index reflecting quality of life according to the individual's own value system. Whereas the PGI requires the individual to respond in the context of their illness, the SEIQOL is one of the few measures of QL in current use in health psychology which could be used equally readily with healthy and ill individuals. Measures in other fields, such as the Satisfaction with Life Scale (Diener et al., 1985), assess QL without reference to illness and can be used successfully with individuals who are ill.

Some measures have been developed specifically for some diseases, including the AIMS (Meenan et al., 1980) for arthritis and the Rotterdam Symptom Check List (de Haes, Van Knippenberg, & Neijt, 1990) for cancer. The authors argue that a more sensitive and acceptable measure of QL can be obtained in this way. This reflects the design of disease-related QL measures, depending on assessment of symptoms and limitations in function as a major factor in QL. Where health-related QL measures assume a value system, this is usually based on assessment of emotional state, symptoms, and disability and the measure offers a method of combining these values. So, for example, the QALY gives values for each combination of distress and disability, and this can be done for individuals with diverse diseases.

It is clear that QL comes quite close to the WHO concept of handicap or to a combination of disability and handicap. There has been some attempt to measure handicap (e.g., the London Handicap Scale; Harwood, Gompertz, & Ebrahiam, 1994) and some measures clearly combine disability and handicap (e.g., the Sickness Impact Profile (de Bruin, de Wilte, Stevens, & Diederiks 1992) or the Functional Limitations Profile (Patrick & Peach, 1989). It is unlikely that there will be agreement on measurement while there continues to be debate about the constructs to measure. Although the construct of QL would appear to have value as a global measure of health outcome, it may mask the underlying processes as proposed by the WHO model. The WHO model proposes causal links between impairment, disability, and handicap rather than a homogeneous single construct and, further, allows the possibility that factors which may moderate the relationship between impairment and disability may be different from those that moderate the relationship between disability and handicap. Thus, the choice of measure, given the current stage of development of theory and measurement, is likely to be determined by whether one is seeking a simple health outcome measure or to understand the processes determining outcomes.

8.04.3.2 Illness Cognitions

The dominant models of response to illness, including stress and coping (Lazarus & Folkman, 1984), social-cognitive (Bandura, 1997) and self-regulation models (Leventhal et al., 1997), agree that individuals develop their own mental representations of the condition and it is these representations that guide the response. Models vary in the cognitions specified and in the level of measurement achieved.

Some address illness simply as a further example of a stressor and consider the degree of threat, outcome expectancies, perceived controllability, etc. as they would for any stressor. Leventhal et al. (1997) have attempted to characterize illness cognitions *per se*, and provide the most extensive work on this topic. They have identified five representations commonly occurring in individual representations:

(i) identity—the label and symptoms associated with the illness;

(ii) time-line—the pattern of change over time, especially whether it is acute, chronic or fluctuating;

(iii) cause—attributions for the illness;

(iv) consequences—the actual and expected consequences;

(v) control/cure—the extent to which the illness can be controlled or cured.

Their work was based initially on open-ended questions and qualitative analyses from which they developed guidelines for interviews (Leventhal & Cameron, 1987). More recently, Weinman, Petrie, Moss-Morris, and Horne (1996) have developed a questionnaire assessment of these five components of representations, the Illness Perceptions Questionnaire, using psychometric techniques to establish basic properties such as internal reliability of the scales. They have demonstrated that the scales have predictive and construct validity, finding that these cognitions predicted subsequent behaviors in patients post-MI as would be expected within the self-regulation model (Petrie, Weinman, Sharpe, & Buckley, 1996).

Weinman et al.'s analysis assumes but does not test the five-component structure found by Leventhal et al. It also assumes a dimensional structure, with each of the five types of representation being distributed along a numerical scale. There are other examples of assessments of illness cognitions which start from different premises.

Turk, Rudy, and Salovey (1986) used factor analytic methods implying an underlying dimensional structure, and found support for four dimensions: seriousness, personal responsibility, controllability, and changability. Although these factors have not proved entirely reproducible in subsequent studies, the degree of overlap between their factors, as characterized by the content rather than the labels for the factors, and the components proposed by Leventhal et al. is impressive. Thus, their controllability construct matches Leventhal et al., control/cure.

Other measures address single constructs other are still compatible with the Leventhal et al. model. Thus, Felton, Revenson, and Hinrichsen's (1984) measure of "Acceptance of Illness" appears to examine the consequences of the illness, containing items such as "my illness makes me a burden on my family and friends" and "I have a hard time adjusting to the limitations of my illness." Many measures address the control construct, including Wallston's recent form C adaptation of the Health Locus of Control scales for people with chronic disease (Wallston, Stein, & Smith 1994), scales for specific groups such as those with diabetes (Bradley, Brewin, Gamsu, & Moses, 1984), and those with the prospect of recovery from disabling conditions (Partridge & Johnston, 1989).

There are alternatives to the dimensional structured approach. Instead of building a representation of the illness from components, it may be useful to examine the prototypes used in evaluating new conditions (Bishop & Converse, 1986). So, for example, Lalljee, Lamb, and Carnibella (1993) have found seven clusters of illness prototypes. This type of analysis may prove useful in understanding responses to ambiguous sets of symptoms where patterns of response may be different to those where symptoms are more clear-cut.

8.04.3.3 Coping with Illness

Coping is defined as what people do to try to minimize stress and is commonly seen in health psychology as problem-focused, that is, directed at reducing the threats and losses of the illness, or emotion-focused, namely directed at reducing the negative emotional consequences. Perhaps the best known measure of coping is the ways of Coping Questionnaire, developed by Folkman and Lazarus (1980). They used factor-analytic procedures to establish the dimensional structure, but later analyses have produced different numbers and types of factors.

Many different coping styles have been identified and measured and contrasts are made between avoidant and attention coping, between active and passive coping, and between behavioral and cognitive coping. The COPE (Carver, Scheier, & Weintraub, 1989) attempts to represent all of these aspects of coping in a multidimensional inventory giving scores on 13 conceptually distinct types of coping. Further, the measure can be used to assess coping style, a dispositional measure of habitual ways of coping, or to assess coping strategy, the methods of coping used to address a specific stressor such as a current illness. The disadvantage of the comprehensiveness of the measure is that it is quite long, appears repetitive, and can seem burdensome to people who are ill. Carver (1997) has therefore published a shortened version which has proved more acceptable while retaining the multidimensional features of the measure.

Other measures address specific forms of coping, for example, Miller's (1987) measure of monitoring and blunting, or they deal with specific clinical conditions, such as Watson et al.'s (1988) assessment of coping styles employed by people with cancer.

Investigators choosing a measure of coping need to consider the compatibility of the measures with their theoretical perspective, the range of scores available, the acceptability of the measure to their clinical group and, possibly, the need to measure not only coping with the illness, but also coping with stressful forms of health-care.

8.04.4 MEASURES USED IN HEALTH-CARE CONTEXTS

People receive diverse forms of health-care, ranging from health checks, through consultations about minor symptoms, investigations of ambiguous symptoms, receiving diagnoses with threatening implications, enduring complex, painful, uncomfortable, or inconvenient forms of treatment, to being maintained on life-support systems. Investigations in health psychology examine factors resulting in individuals seeking health-care or accepting care that is offered, they explore the nature of the process of delivery of health-care, and they evaluate the psychological and behavioral outcomes of health-care.

For most forms of health-care, the recipients will be ill and therefore the questions and measures addressed in the previous section will also be pertinent. For those undergoing health checks or screening procedures, issues relevant to healthy individuals may have more relevance.

A major source of behavioral variation in health-care is due to the health professionals or providers as well as to the patients (Marteau & Johnston, 1991). As health services move towards implementation of evidence-based care, the assessment, explanation, and modification of their behavior is likely to be an increasing focus of investigations (Grol, 1992, 1997).

8.04.4.1 Measuring the Process of Health Care

The process of health-care delivery includes policy and management decisions and behaviors which occur at a level that tends to be outside the normal range of health psychology. The focus is primarily at the point of delivery, in the interaction between the patient and the health-care provider.

8.04.4.1.1 Communications between patients and providers

There is ample evidence that the nature and style of communications can determine the outcomes of health care (Ley, 1988; see Chapter 8.03, this volume). Various methods have been developed to describe and characterize the interpersonal communication process, using raters to assess records (audio, video, or typed transcripts) of the communication. Roter and Hall's Interaction Analysis (1989) based on the original work by Bales has been used to assess the components of interpersonal communication, such as giving information, asking questions, etc., whereas Stiles' Verbal Response Mode analysis (Putnam, Stiles, Jacob, & James, 1985; Stiles, 1989) identifies eight mutually exclusive modes of responding, including disclosure, interpretation, confirmation, and reflection. Other rating scale measures have been developed to assess the performance of health professionals against verbal and nonverbal performance criteria used in training (Maguire & Selby, 1989) or to assess the degree to which a doctor is patient- or doctor-centered (Byrne & Long, 1976). In each case, the methods are assessed in terms of inter-rater reliability and the predictive value of the assessments.

Methods of assessing written communications have also been developed (Ley, 1988). A major issue has been the assessment of intelligibility of written information such as leaflets for patients and some methods, such as the Flesch formula, can readily be applied to text using widely available word-processing software.

8.04.4.1.2 Uptake and adherence

When patients do not take up an offer of health care or do not adhere to recommended advice or treatment, the process of health care is interrupted. Although the assessment of uptake *per se* is fairly easy from health care records, it may be more difficult to ascertain whether a failure of uptake is due to not receiving the invitation, not understanding the invitation, not being able to accept the health care offered, or refusing the health care offered. These different patterns of interrupted health care have different causes and may have different effects on health outcomes; for example, Marteau et al. (1992) found different patterns for women refusing tests in pregnancy compared with those who simply omitted to have the test.

Similar contrasts have been drawn between intentional and nonintentional nonadherence to medication regimens and Horne (1997b) has developed a measure that allows separation of the two types of nonadherence. Although self-reports of adherence are widely criticized as being subject to social desirability biasing, they are correlated with other measures of adherence. In addition, all other measures of medication adherence have been criticized. Behavioral observation is limited as no observer can be permanently present, while pill counts and dispensers which record occasions of use can readily be manipulated by the patient who would wish to appear more compliant.

For adherence to advice on behavior change, some observational corroboration may be possible, but with the above caveats. For smoking advice, there are physiological indices such as serum cotinine which are less likely to be manipulated, whereas for dietary advice, measures of weight or serum cholesterol may be relevant. However, none of these measures has a one-to-one relationship with the behavior and they can therefore be misleading.

In sum, there appears to be no easy accepted solution to the problem of measuring adherence. It may be sufficient to use one, probably a self-report measure, for most investigations, but if this is a key variable, then more than one method should be used if possible.

8.04.4.1.3 Behavior of health professionals

Two main areas of behavior of health professionals have been investigated: their adherence to recommendations and the amount of stress they experience. As for patient adherence, it can be difficult to measure what cannot be observed and self-report may prove useful. However, some behaviors, such as hand hygiene, are observable and have been investigated. Other behaviors, such as drug dispensing, are likely to be assessable from patient or ward records.

Stress in health professionals has been investigated because of the recognition that working with people who are ill may be stressful and a concern that stressed professionals may be less able to deliver effective health care (Payne & Firth-Cozens, 1987). Perceived stress and the emotional impact can be investigated using conventional measures such as the Perceived Stress Scale (Cohen, Kamarck, & Mermelstein, 1983) or measures of mood or emotional state. In addition measures of occupational stress have been used, for example, the nursing stress index (Cooper & Mitchell, 1990), and the Maslach Burnout Inventory (Maslach, 1982) has been widely used to evaluate disabling levels of stress.

The effects of stress on performance of tasks has been assessed using self-reports of errors or by using cognitive tasks such as reaction time tasks as a proxy for the real task. The prevalence of major errors, such as in drug prescribing, can be investigated from health care or medicolegal records (Vincent, Ennis, & Audley, 1993).

8.04.4.1.4 Psychological and behavioral interventions

The recording of psychological interventions is not normally regarded as a measurement issue. However, a wide range of psychological and behavioral interventions is used in health care and it becomes increasingly important to be able to at least classify interventions. In the field of preparation for stressful medical procedures there are many interventions, for example, procedural information, sensory information, cognitive coping, and relaxation (Johnston & Vogele, 1993). For methods to be replicable and discriminable, they need to be characterized in sufficient detail to be able to at least classify which type of intervention is being used and perhaps to be able to rate interventions on the extent to which they use each mechanism (e.g., giving information, providing behavioral instruction, and training in relaxation).

This issue becomes increasingly urgent as high-profile reports of investigations of such interventions are published without any data, descriptive information, or methods of accessing such information about the interventions being provided (Johnston, 1995).

8.04.4.2 Health Care Cognitions

The beliefs, attitudes, and expectations of patients and health care providers to various aspects of health care have been investigated, often with a focus on the potential mismatch between patient and provider of health care or on beliefs likely to interfere with effective health care delivery.

8.04.4.2.1 Patients' health care cognitions

Some of patients' health care cognitions are those already considered with reference to health and illness; for example, perceived effectiveness of health care may be assessed in social cognition models of health behaviors, and perceived cure and controllability is a key element in illness cognitions.

Patients' expectations of health care have been investigated in terms of their general preference for managing their own treatment and the information relevant to their condition (Krantz, Baum, & Wideman, 1980) as well as preferences for care in a specific consultation with a doctor (Salmon & Quine, 1989). In each case, the scale has been validated using factor-analytic procedures and in both, items referring to provision of information have loaded on different factors from items dealing directly with treatment issues. Thus, there is some evidence that distinct elements of patients' preferences for medical care are being investigated.

In addition, there are more general measures of attitudes toward physicians and towards medicine (Horne, 1997a; Hulka, Zyzanski, Cassel, & Thompson, 1970; Marteau, 1990). Measures that evaluate a specific consultation are considered as health outcomes below.

Health care cognitions also include assessments of the stressfulness of receiving health care. For example, the Hospital Stress Rating Scale (Volicer & Bohannon, 1975) provides scaled values of the perceived stress associated with a large number of hospital experiences.

8.04.4.2.2 Providers' health care cognitions

As for patients' cognitions, health care providers' cognitions have also been investigated using the constructs of social cognition models. For example, their self-efficacy for providing dietary instructions was examined in the context of reducing serum cholesterol (Schucker et al., 1987). Investigators have also investigated their views of their working environment in the context of investigations of the stressfulness of caring for patients (Parkes, 1982). Further, measures of clinicians' attitudes to different patients groups have been developed; for example, St Lawrence, Kelly, Owen, Hogan, and Wilson's (1990) measure of attitudes to AIDS gives an index of favorableness of attitudes and one of willingness to interact with them in a clinical situation.

8.04.4.3 Health Care Outcomes

The main health care outcomes are health outcomes and these are measured as measures of illness as described in Section 8.04.3.1. In addition, health care outcomes include measures of health care utilization such as length of stay, number of primary care consultations, or use of medication; these measures can normally be obtained from health care records. For some investigations, these indices will be converted into health care costs, using the techniques of health economics. Delay in receiving health care, such as following MI, or deprivation of health care, especially preventive health care, may also constitute relevant outcomes. Where health care is directed at enhancing adherence with a prescribed regimen of medication or changing health-related behaviors such as diet, adherence to advice may also be an outcome, although it is more commonly seen as part of the process of health care. Where the objective is to impart information, measures of knowledge may constitute an outcome, although one might expect this improved knowledge to impinge on health or illness outcomes or on utilization of health care.

An important health care outcome is patient satisfaction. The most commonly used measure of satisfaction with a medical consultation is the Medical Interview Satisfaction Scale (MISS) (Wolf, Putman, James, & Stiles, 1978) which assesses affective, behavioral, and cognitive aspects of the consultation. Most measures of patient satisfaction have problems of validity and scaling as responses are skewed towards favorable ratings. Ware and Hays (1988) have found that measures of satisfaction are less skewed and therefore have improved psychometric qualities if respondents are asked to assess the excellence of the medical consultation rather than their satisfaction with the consultation.

8.04.5 MEASURES USED IN ALL CONTEXTS

Some measures are used in all contexts in health psychology.

8.04.5.1 Stress, Life Events, and Emotional States

Measures of stressors such as Life Events Scales (Holmes & Rahe, 1967), Impact of Events Scales (Horowitz, Wilner, & Alvarez, 1979), perceived stress scales (Cohen et al., 1983), or emotional states (Radloff, 1977; Zigmond & Snaith, 1983) are relevant in all contexts of health psychology. Life events, stress, or emotional states may influence health or the practice of health-related behaviors, may affect the likelihood of disease, may result from illness, and may be a consequence of health care for patients, their families, and health care providers alike. Thus measures that tap the stress process may be relevant for investigations in all areas of health psychology.

8.04.5.1.1 Social deprivation

Social deprivation has been shown to be related to the performance of health behaviors, to susceptibility to disease, to recovery from disease, and to receipt of health care (Adler et al., 1994; Carroll, Bennett, & Davey-Smith 1993; Carroll & Davey-Smith, 1997). It has been conceptualized in various ways: educational level, occupational status, financial status, socioeconomic status, residence in a deprived area, etc. Given the pervasiveness of this variable, it is important to ensure that it is measured as well as possible in all investigations.

8.04.5.2 Resources

Similarly, the resources that the individual brings to the health, illness, or health-care context are likely to determine how individuals respond. Coping has already been considered in the context of coping with illness, but clearly models of stress postulate that coping responses are likely to moderate the effects of stress and therefore it is appropriate to measure coping in contexts where stress may be relevant.

8.04.5.2.1 Social support

Social support has been conceptualized as directly beneficial, with lack of social support being akin to a stressor or as a resource that buffers the effects of stress (Cohen & Wills, 1985). Social support has been found to predict susceptibility to disease, to moderate the effects of stress, and to influence health and health care outcomes.

Social support has been measured in diverse ways and a major distinction is made between measures of the structure or network available to the individual and the quality or satisfaction with the support available; for example, the Social Support Questionnaire (Sarason et al., 1983; Sarason, Sarason, Shearin, & Pierce, 1987) gives measures of amount and satisfaction with social support. Similarly, there are different types of support with the most common distinction being made between emotional and practical support (Power, Champion, & Aris, 1988), but other forms such as esteem, informational, and companionship have also been distinguished (Cohen & Wills, 1985).

Such measures are difficult to validate, but correlations with relevant other self-report measures supports the construct validity of the scales.

8.04.5.2.2 Individual differences

Individual differences have already been referred to in the context of predicting disease (Section 8.04.2.4) and the confounding effects of negative affectivity in measurement especially in measuring illness (Section 8.04.3.1). Negative affectivity has been measured as trait anxiety (Spielberger, 1983), neuroticism (Eysenck & Eysenck, 1985), or using the scale developed by Watson, Clark, and Tellegen (1988), the Positive and Negative Affect Schedule (PANAS).

Positive affectivity has been found to be independent of negative affectivity and may act as a resource in stressful situations. Similarly, other attributes that may serve this protective function are Dispositional Optimism (Scheier & Carver, 1985, 1987) and self-esteem (Rosenberg, 1989).

8.04.6 FUTURE DIRECTIONS

This chapter has described the main measurement issues in health psychology. As this is a comparatively new area of research and practice, there are problems as well as solutions in many of these areas. However, there is increasing sophistication in measurement in most of the areas covered. In part this comes about simply as a result of increasing experience of the measures, so that gradually issues of reliability, validity, ambiguity, consumer resistance, etc. are identified and tackled. It is to be expected that this process will continue and increasing experience with measures and ever widening areas of application will lead to improved measurement. Measurement in health psychology will also benefit from the changes in technology that will affect most areas of psychology. Increasingly, testing will be computerized and as a result more relevant information will be gathered without overburdening the respondent. Advances in technology will also lead to more information, both behavioral and physiological, being gathered in the client's own environment, rather than the laboratory or clinic.

However, it is expected that improvements will increasingly come about because of more fundamental changes in how questions are asked and in the tools used to answer them. As indicated, many measurement problems arise because of a lack of specificity in how theoretical concepts should be operationalized. Although still far from perfect, theories are becoming more specific and directly address issues of operationalization (see Chapter 8.01, this volume). If this trend continues then there should be an increasingly good fit between theory and measure, and also increased comparability across different domains when the same theory is applied to different problems. A tool that is starting to increase our understanding of what we measure (particularly in questionnaire design) and how to improve it is the widening use of complex multivariate methods such as structural equation modeling and the related procedures of confirmatory factor analysis. A central problem in health psychology is the very substantial overlap between concepts; in particular, the real possibility that much of what is measured reflects primarily the pervasive effects of negative affectivity. The application of appropriate statistical techniques should see this issue resolved and is likely to lead to a reduced set of health-related individual difference measures and a better focused series of specific measures.

ACKNOWLEDGMENT

Some parts of this chapter have been influenced and informed by the work of John Weinman and Stephen Wright in co-authoring *Measures in health psychology: A user's portfolio* (Johnston, Wright, & Weinman, 1995).

8.05.3 SUMMARY 150

8.05.4 REFERENCES 150

8.05.1 INTRODUCTION

With the increasing focus on cost-containment and cost-effectiveness, clinical health psychologists are finding it increasingly necessary to document the value of their services. This documentation requires relying not only on empirical data to demonstrate the impact of treatment, but also on research designs which are rigorous yet feasible in active clinical settings where funding may not be available to support resource-intensive efforts. Given the emphasis of health psychology on the individual's well-being, it would seem incumbent on such research to link the patient's perspective with objective clinical outcomes as well as cost. Such linkage would also be consistent with the biopsychosocial model which drives much of health psychology theory and practice. The purpose of this chapter will be to discuss key designs, considerations, and challenges of doing outcomes studies of interventions in a clinical health psychology and/or medical setting. Although similar issues will be relevant for health psychology research which is correlative/predictive in nature, it is beyond the scope of the present chapter. Further information on some of the various concepts and designs discussed can be found in Volume 3.

8.05.2 IMPLEMENTING RESEARCH IN A CLINICAL SETTING

8.05.2.1 Key Considerations for Meaningful Research

Active clinical settings present an inviting paradox to the health psychologist. On the one hand, they have the ultimate resource for relevant outcomes research: an ample source of patients. Further, there is an obvious potential to link patient outcome data to clinical and cost data. The challenge of such settings is implementing data collection efforts from patients which are both externally and internally valid, often without financial and personnel resources dedicated to research endeavors. Thus, key considerations in study implementation need to be planned and integrated into the daily clinical routine so that the resulting data yield meaningful and useful glimpses into the patient's experience of illness and its management. The considerations which are crucial to successful study implementation (Table 1) will be discussed briefly.

8.05.2.1.1 Ask a meaningful research question

Since any well-done research endeavor is likely to require substantial effort and organization, it would be important that the research be motivated by research questions which are meaningful to patients, providers, payers, and other parties. A clinical setting provides the health psychology researcher with ample opportunities to hear about potentially interesting research issues and to develop hypotheses about what social and behavioral factors would be worthy of exploration in a formal study. By listening to patients, their caregivers, healthcare providers, payers, and others, researchers can develop questions which are responsive to current forces in healthcare delivery and health enhancement in general. Meaningful research questions can be developed in response to maintaining an open ear when interacting with patients and others in the clinical setting. Other more formal approaches might include focus groups (Morgan, 1988) and semistructured individual interviews with people with various relevant perspectives.

8.05.2.1.2 Have a strong theoretical foundation

A reasonable background of both knowledge and theory would be necessary conditions for a research study to be worth the effort and resources it will cost. Such a background can be gleaned by consulting with health psychologists who have a current and broad foundational understanding of models of change or growth from fields such as health education, public health, clinical and health psychology, and psychiatry. These models would provide a necessary foundation for hypothesizing what psychosocial and medical factors would be relevant and thus should be measured (Slife & Williams, 1997). This understanding might be supplemented with recent literature reviews as well as searches of computer databases of medical and psychological publications.

8.05.2.1.3 Measure appropriate outcomes

In beginning to plan a study with a strong theoretical foundation, one must select relevant outcomes. This selection process should also be informed by clinical acumen and patient experience. Focus groups (Morgan, 1988) with providers and patients can be helpful in identifying germane outcomes. This method usually identifies relevant groups whose perspective should be considered and begins with a series of open-ended questions. The underlying theme of focus groups is to expand the realm of possibilities rather than to contract them. One continues focus groups and various provider and patient subgroups until the information gleaned becomes redundant (Morgan, 1988). Focus groups can also be useful for pretesting questionnaire packets and for selecting one questionnaire among many which ostensibly measure the same thing. For example, there are numerous measures of functional status which might be used in an outcomes study. In the pilot-testing phase of a study evaluating the impact of two psychosocial interventions (Schwartz, 1994; Schwartz & Rogers, 1994; Schwartz & Sprangers, under review), Schwartz pretested a set of functional status measures, and asked chronically ill patients to track their mood and energy level before and after completing each measure.

Table 1 Key considerations for successful study implementation.

Consideration	*Method for achieving*
a. Meaningful research question	Listening to patients and clinicians, literature review, attenting to regulatory forces in health care delivery
b. Theory-based	Literature review; expert consultation
c. Appropriate outcomes	Focus groups
d. Appropriate study design	Match with research question and assumptions (see Table 2)
e. Response rate	Total Design Method
f. Complete data	Telephone follow-up
g. Appropriate analysis	Involvement of statistician when planning study
h. Statistical power	Involvement of statistician when planning study
i. Dissemination to appropriate audiences	Peer-review journals; patient education; managed care journals

The measure which was selected finally was the one which was the least depressing and was rated by patients as asking questions they deemed pertinent to their physical well-being.

8.05.2.1.4 Use an appropriate study design

Although collecting data from consecutive patients who come into a clinic might be considered research by some people, most professionals would agree that studies must be designed before they are implemented if they are to result in data worth analyzing. It is believed that study design is a crucial stumbling block for many aspiring researchers, and an entire section of this chapter has been devoted to describing five study design options which can be implemented feasibly in busy clinical settings (see below).

8.05.2.1.5 Maintain a high response rate

Ascertaining the generalizability of the study results will be an important consideration in assessing the impact that it may have. Studies which lose a large proportion of eligible participants are necessarily suspect of suffering from selection bias which may hamper the investigators' ability to make any valid conclusions about the treatments being evaluated. Further, substantial drop-out rates can result in more time required for accrual and more costly resources required to implement studies. Thus, planning carefully to maximize response rate would be a necessary condition to successful research.

In his Total Design Method, Dillman (1978) provides an accessible and feasible method which integrates the large literature on survey research to specific steps for assuring a high response rate. These steps can be easily implemented by the clinical researcher. For example, Dillman provides details regarding the letter which is sent to patients to inform them and invite them to participate in a given research study. He outlines the information which should be included in each paragraph, the letterhead parameters which have been documented to enhance response rate, the color ink which should be used to sign the letter, whose names should grace the letter, and the way in which the letter should be folded. Dillman (1978) provides a similar level of detail regarding preparation of the questionnaire booklets. Although this level of detail might seem unnecessary, he documents the increased percentage of response rate which results from their consideration. If one follows Dillman's protocol, one can be assured of a 90% response rate. Indeed, following these steps very carefully has allowed our group to maintain a high response rate in a number of studies by mail.

8.05.2.1.6 Maintain complete data

Missing data can pose significant problems to data analysis and interpretation. Most self-report questionnaires require data on at least 75% of the items within a subscale to allow imputation of a subscale score. Similarly, most statistical methods require complete data to include a participant's data in the analysis. Although some statistical methods can accommodate missing data (e.g., growth curve; Francis, Fletcher, Stuebing, Davidson, & Thompson, 1991), the meaning of the missingness can be an important consideration. For example, if data are "informed" missing, then their absence is indicative of some notable cause, such as dying during the course of the study. If they drop out due to health problems or access to care, then their missing data would also be informative. Thus, it is incumbent on the health psychology investigator to maintain complete data as much as possible, and to document reasons for drop-outs and missing data.

Developing a good rapport with study participants can be crucial for attaining complete data. This rapport may be developed initially in an intake interview, and maintained via telephone follow-up. For example, if a participant has not returned a questionnaire packet within two weeks of mailing it out, the investigator would be well-advised to inquire via telephone and to negotiate a date by which the participant is able to return the completed packet. Similarly, if the packet is returned but there are items which have not been answered, a respectful phone call can be beneficial. In general, it has been found that such calls are perceived by patients to be indicative of the seriousness and meaningfulness of the research endeavor, and they are cooperative in answering the missing items. If the patient purposefully left the item blank, then the investigator should respect the confidentiality of the patient, code the item as "refused," and not press the participant for an answer.

8.05.2.1.7 Plan and implement appropriate statistical analysis

A well-planned investigation would include planning the statistical analysis before the study is implemented. Such intention would ensure that the appropriate data (e.g., covariates, predictors, and outcomes) are collected, and that the research questions will be addressed adequately by the statistical analysis. It is recommended to include on the research team a professional who has expertise in statistical analysis. This person's expertise should be included at the planning stage of any study.

8.05.2.1.8 Plan study with adequate statistical power

By planning the statistical analysis when the study's research questions are being defined, the thoughtful investigator paves the way for adequate statistical power. Simply stated, an investigator's power to detect meaningful differences depends on three parameters: the sample size, the magnitude of the effect which is deemed clinically significant, and the inherent variability of the outcome measure. The power curve is exponential, requiring few subjects per group for large effects, and large numbers of subjects per group for moderate and small effects (Figure 1) (Cohen, 1988; Pocock, 1983). It is recommended that power calculation be used during the planning phases of a study by a professional who has expertise in statistical analysis, or with the aid of software designed for behavioral science studies (e.g., Bornstein & Cohen, 1988).

8.05.2.1.9 Disseminate findings to appropriate audiences

One of the most important products of a research study is developing vehicles for disseminating study results. Such dissemination should take place through peer-reviewed professional journals, a mechanism which can enhance the state of knowledge in the broader arena. Other mechanisms exist which can influence other highly relevant audiences. For example, there are private foundations which focus on a specific disease and which would provide conduits by which investigators might implement patient educational programs based on the results of their research. There might also be access to other healthcare providers and payers by publishing jargon-free articles in managed care journals and health management organizational newsletters. The more mechanisms by which access to study results can be provided, the more influential such results can be. Even negative (i.e., nonsignificant) findings can be informative, so investigators are to be encouraged to disseminate study results in all cases.

8.05.2.2 Study Designs to Evaluate Clinical Interventions

Thus far, important considerations in successful study implementation to enhance the external and internal validity of the research endeavor have been reviewed. Although the clinical setting does not necessarily pose challenges to assessing needs or concerns of patient populations, many important research questions may be more focused on how efficacious and cost-effective an intervention may be. Despite the above suggestions, the clinical setting may pose challenges to implementing the standard randomized controlled trial. In this design, eligible patients are approached and asked to participate in a trial in which they will be randomized to one of two treatment arms. Study designs which maximize statistical power are placebo-controlled randomized trials with longitudinal follow-up (Kraemer & Thiemann, 1989). Given the ethical, theoretical, and practical problems with placebo-controlled studies (Schwartz, Chesney, Irvine, & Keefe, 1997), the modern investigator often may be forced to consider statistical power issues in the context of intervention studies of two active treatments, such as standard care as compared to an experimental treatment or psychological adjunct (Figure 2(a)). The more one controls for nonspecific effects, the smaller the anticipated effect size and hence the larger the sample size requirements (Kazdin & Bass,

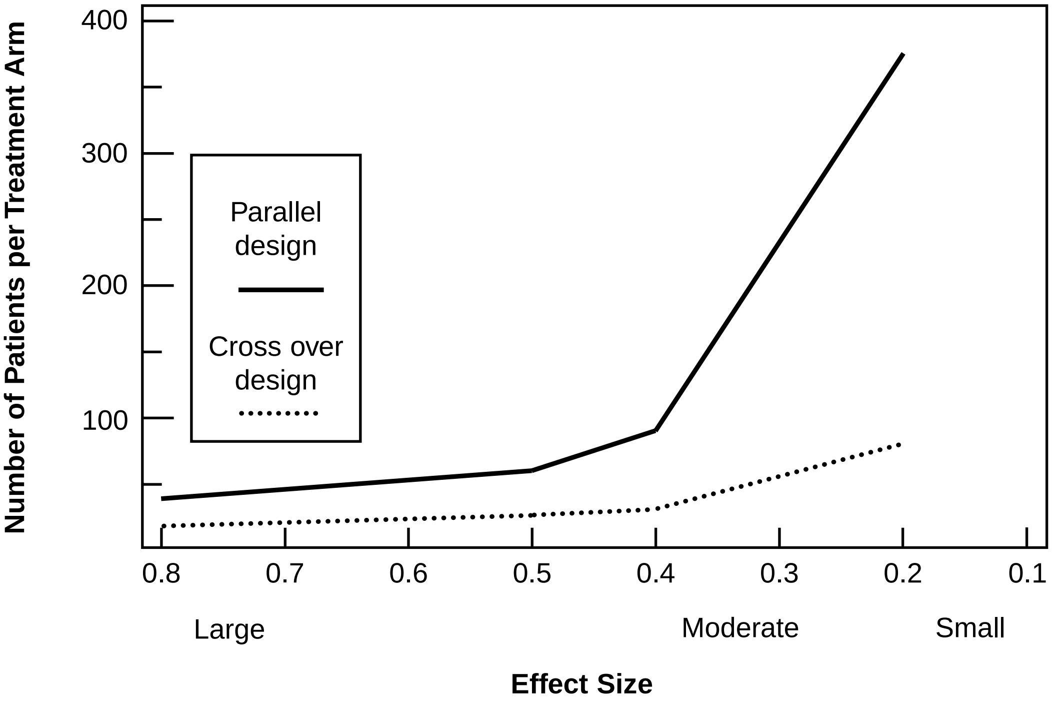

Figure 1 Statistical power curves for parallel design and crossover trial. This plot shows how the sample size requirements for a study increase with the decreasing magnitude of the anticipated effect size. Using a crossover design can reduce the required sample to approximately one-quarter the number of subjects as a parallel-arm study for the same power (Fleiss, 1986). This estimation assumes that the within-subject variability is equal to the between-subject variability.

1989). Similarly, the more the intervention is tailored to the individual patient, the more heterogeneous the resulting comparison groups. This heterogeneity also reduces the statistical power due to the increased variability in the outcomes. The increased cost and challenge of implementing such a large study might lead to considering the several design alternatives outlined below.

8.05.2.2.1 Needs assessment followed by randomized consent

An alternative to the standard randomized controlled trial is the randomized consent design (Zelen, 1979, 1990). In this design, eligible patients are randomized prior to obtaining consent, and consent is obtained for participation in that arm to which the patient has been randomized (Figure 2(b)). This design might be beneficial in a clinical setting where the efficacy or cost-effectiveness of an adjunctive treatment which is a reimbursable clinical service is evaluated. In this case, "reimbursable" refers to the idea that a third party (i.e., insurance company) would deem the service worthy of coverage by the individual's healthcare insurance. Such a concern is particularly relevant in countries which do not have universal healthcare coverage (e.g., the USA). By using a randomized design, the statistical comparability of the two treatment arms is ensured, thereby reducing the systematic error encountered in more quasi-experimental designs. The primary caveat of the randomized consent design is that it is feasible only if participants will be highly likely to accept the treatment to which they have been randomized. This caveat is due to the intention-to-treat principle of randomized trials: that is, that patient data are analyzed according to the intervention to which they were assigned, regardless of how much of the treatment they actually received. This principle ensures that the more consistent the efficacy (i.e., effectiveness and feasibility) of an intervention, the more ecologically valid the representation of the real-world impact it is likely to have.

To ensure that the participants will be highly likely to accept the treatment to which they have been randomized, implementing a needs assessment survey of clinic patients is suggested. This survey can be used to help determine the psychosocial needs and meaningful interventions for a given target population (Edwards & White, 1987). Data from such surveys can also be used to evaluate the sociodemographic and medical correlates of expressed needs (Kraft,

Figure 2 Research designs which would be feasible to implement in an active clinical setting. (a) Schema for a standard randomized controlled trial for the sake of comparison with the subsequent designs. (b) Schema for a needs assessment survey followed by a randomized consent design. (c) Schema for the three-arm crossover design, which allows one to evaluate the impact of duration of treatment on outcomes. (d) Case–control design which would require matching patients on relevant sociodemographic and medical characteristics. (e) The Solomon four-arm pre–post design controls for maturation effects and investigates the impact of salience cuing on treatment outcomes. (f) Schema for a pre–post one-group design which is the simplest and least expensive study to implement. This study allows one to evaluate patient factors associated with better treatment outcomes.

Freal, & Coryell, 1986). By beginning with a needs assessment survey, a needy target population can be identified for a specific trial who would be likely to want the intervention(s) being evaluated (Figure 2(b)).

8.05.2.2.2 Three-arm crossover design

Given the difficulty in randomizing patients to a placebo–control condition, Schwartz et al. (1996) have proposed a randomized three-arm variation of a standard crossover trial. This design allows evaluation of treatment, order, and dose–response effects. In the first two arms, patients would receive active treatment followed by a control condition (arm "a" in Figure 2c), or vice versa (arm "b" in Figure 2(c)). The patients randomized to the third arm (arm "c" in Figure 2(c)) would receive the active treatment for the entire duration of the other treatment arms (i.e., treatment and control). This arm would allow the investigator to address the longer-term effect of the intervention, without dramatically increasing the sample size.

The control condition in the first two arms (i.e., arms "a" and "b" in Figure 2(c)) would be a wait-list which could involve standard care or no treatment. The decision about whether to use a standard care or no-treatment wait-list control would depend on the usual treatment approach for the study population and symptom complex. If there were a standard treatment for the symptom complex (e.g., pharmaceuticals, support groups, antidepressants, etc.), then the wait-list patients would have normal access to them. If the syndrome is one that does not interfere significantly with daily life and is not threatening to health then a no-treatment control would be appropriate. If the trial population is in crisis, then the control group would get standard care.

Since crossover trials compare the impact of an active treatment to standard care and/or wait list control, the designs avoid the need to create a placebo–control. Thus, the three-arm crossover similarly minimizes the ethical dilemma by providing treatment to all patients. The enhanced statistical efficiency of the crossover design would allow the use of individually-tailored interventions, and thus increase the clinical validity of the trial results. Such treatment protocol heterogeneity would normally reduce the statistical power of the trial and lead to an expensive increase in the number of patients required to detect a difference between treatments. However, crossover designs use patients as their own controls and are thereby statistically efficient: they require approximately one quarter the number of patients per study arm as those required for a standard parallel design (Figure 1, Fleiss, 1986). This estimation assumes that the within-subject is equal to the between-subject variability. This increased power would offset the reduced statistical power of the protocol heterogeneity.

The proposed three-arm crossover design allows for an examination of dose–response relationships, whereas the standard crossover trial limits the investigator's ability to learn about the effects of longer-term intervention. The three arms provide information about the effects of shorter-term interventions (i.e., arm "a" or "b") and about longer-term interventions (i.e., arm "c"). The investigator might seek to evaluate the maintenance of effects over time (i.e., carryover effects) by shorter-term interventions using data from arm "a" or design the study to include a washout period between treatment and follow-up so that the follow-up could be a clear no-treatment comparison condition. Consequently, treatment outcomes should be measured pre- and postintervention as well as before and after the washout and no-treatment periods. Thus, the proposed design responds to the standard problem of crossover designs, that of not allowing the investigator to examine whether continued adherence to an intervention produces benefits over a long period of time or follow-up. This use of the three-arm crossover trial data is similar to an approach used by Thoresen (1991) to evaluate the long-term impact of a behavioral intervention for postinfarction patients who had participated in a crossover trial. They were able to show that the larger the "dose" received of the behavioral intervention, the greater behavior change and health benefit.

Finally, the three-arm crossover design can allow the investigator to evaluate order effects, which may prove illuminating for hypothesis generation. For example, assume that condition "a" is nonspecific support (e.g., social support), condition "b" is coping effectiveness training (i.e., the experimental intervention), and condition "c" is two cycles of the coping effectiveness training. The design is: AB, BA, and BB. Suppose that analysis of the results revealed that AB was better than BA and BB. The interpretation, framed as hypothesis generation, might be that social support prepared patients for the coping skills training, whereas coping skills training given first inadvertently increased resistance in some patients. Therefore, this three-arm crossover design could identify possible timing or staging effects of the different therapies.

The appropriateness of the three-arm crossover trial will depend on the objectives of the research. If the intervention is not expected to have extended carryover effects (e.g., acupuncture, massage), then no washout period will be required. If the intervention is expected to have brief carryover effects (e.g., pharmacotherapy), then a brief washout period may be necessary. If the intervention is a cognitive-behavioral treatment for stress management, then a washout period may not be feasible because it may not be possible to remove the effects of the exposure. If the objective is to study carryover effects, then a standard parallel-arm design would be appropriate (i.e., treatment vs. control with no crossover). For example, the experimental treatment, best standard care, and a wait-list control or usual care (if the latter is not the same as the comparison condition) could be compared. The latter design will be expensive to implement due to the sample size requirements in parallel-arm trials comparing active treatments (i.e., small effects sizes, see Figure 1). Further, it may not be feasible among proactive patients who refuse to participate if randomized to a wait-list control. The three-arm crossover design is a feasible and appropriate design if carryover effects are not the primary endpoints. It represents one of several possible approaches to design.

8.05.2.2.3 Case–control

Borrowed from the field of epidemiology, the case–control design can be useful for health psychology research on interventions where some naturalistic assignment has occurred. In this design, patients are naturalistically "exposed" to one of the interventions under study and followed over time to determine the effect of the intervention (Figure 2(d)). This design might be used in cases where similar patient groups at difference sites receive distinct interventions. For example, if two sites of a managed care organization had similar patient populations in a diabetes clinic, and only one of the clinics implemented a patient education self-management program. Patients from both sites could be followed over time to evaluate the patient education program.

8.05.2.2.4 Solomon four-group pre–post design

This design allows the explicit consideration of external validity factors (Campbell, 1963). By paralleling a standard pretest–post-test control group design with experimental and control groups lacking the pretest (Figure 2(e)), the main effects of both the intervention and testing can be evaluated, as well as the interaction of the intervention and testing. This design consequently allows for an investigation of the impact of salience cuing on treatment outcomes. For example, measuring an outcome requires asking patients to self-report about that outcome. Thus the outcome's salience may be increased as a function of study participation, thereby leading to a shift in internal standards (i.e., response shift as described subsequently) on behalf of study participants. The Solomon four-group design would provide a vehicle for examining this aspect of response shift in clinical health psychology research.

8.05.2.2.5 Pre–post one-group design

Many investigators may not feel that they have the expertise to implement studies with more complex designs. Consequently, they rely on recruiting consecutive patients for treatment evaluation studies and asking patients to self-report on various quality-of-life outcomes before and after the intervention (Figure 2(f)). Because there is no comparison group, such data are not appropriate for testing the effectiveness of an intervention. However, this design can facilitate correlative or predictive studies in health psychology which seek to understand which factors are associated with better outcomes. One example of this use of the pre–post one-group design was a study done by Mohr et al. (1996) in which they examined how patient expectations were related to treatment compliance among a cohort of multiple sclerosis patients. They found that adverse events and unrealistic expectations were important predictors of treatment compliance in 86% of patients initiating an immunomodulating therapy. This use of the pre–post one-group design exemplifies how clinically relevant information can be gleaned with this simple and feasible research design.

8.05.2.3 Selecting the Appropriate Study Design for Evaluating Treatment Intervention Effects: Balancing Research Questions and Assumptions

The above five study designs are reasonable alternatives to randomized controlled trials for health psychology research. However, selecting the appropriate design will require balancing the research question being asked as well as the assumptions on which each design relies (Table 2). Although the first five study designs address the relative effectiveness of treatment A vs. treatment B, they differ in their assumptions about patient characteristics. For example, the standard randomized controlled trial assumes that patients will accept randomization to the control group, and will not seek alternative and similar treatments to the experimental group due to resentful demoralization (Cook & Campbell, 1978). In contrast, the randomized consent design only asks that patients accept the singular treatment option to which they have already been randomized. Thus, the former may take longer to accrue participants if the control group is obvious. On the other hand, the randomized consent design is only feasible if the researcher is fairly certain that patients will be likely to accept the treatment option to which they have been assigned.

A common assumption of randomized designs is that the random allocation method results in groups which are similar on sociodemographic and medical characteristics. As this is not always the case, stratification may be necessary for the crucial characteristics. Covariate adjustment can be done in the analysis phase for other pretreatment differences which occurred despite randomization. Although covariate adjustment can be done in both case–control and pre–post one-group designs, the former would benefit from matching study participants on relevant sociodemographic and medical factors to enhance the comparability of the two groups. This matching will prevent confounding due to differential representation of various prognoses by study arms, a design problem which cannot be resolved with covariate adjustment. One example of such a problem would be comparing the impact of a behavioral intervention on people with epilepsy, and not matching for location and focality of brain lesions. It is well-known that patients with focal temporal lesions are more likely to be considered as candidates for neurosurgery (Lechtenberg, 1990), and hence have a better psychosocial prognosis than those with diffuse lesions in other parts of the brain. Not matching on such important prognostic factors can lead to unnecessary confounding and perhaps even selection bias.

Given the similarities in research questions and assumptions across the several designs suggested, clinical investigators may need to base their research design selection on characteristics of the context in which they would like to initiate the research study. For example, randomized trials may not be feasible in settings in which there is no support staff to oversee the blind allocation of treatment or vigilant follow-up. In these contexts, the case–control or pre–post one-group designs may be optimal as they would allow one to dovetail data collection efforts to standard clinic visits and can address relevant, albeit limited, questions about treatment outcomes. The clinical investigator therefore has several design options which can facilitate outcomes research despite limited resources. Selecting an appropriate design will require the careful balance of the research question one seeks to ask, the assumptions one is comfortable making, and the constraints imposed by the clinical context.

8.05.2.4 Practical Challenges to Implementing Research in a Clinical Setting

Once an appropriate design has been selected, clinical investigators may wish to begin collecting data immediately. However, there are other practical challenges which they may confront. These challenges reflect the emerging financial and legal considerations which are playing an increasing role in healthcare. Highlighting a few of these considerations should make it easier for potential investigators to prepare for them.

8.05.2.4.1 Who pays for treatments being evaluated?

The appeal of implementing research in a clinical setting is partially founded on the assumption that the cost of such research can be reduced by having it dovetail with standard clinical work. Indeed the goal of outcomes research is to integrate an evaluation process into standard clinical practice and to provide relevant and timely feedback to clinicians so that they might improve the quality of care provided. However, many healthcare payers (e.g., insurance companies) may consider that such attempts to evaluate clinical practice indicate that the practice is "experimental" and therefore not reimbursable. Consequently, the investigator is faced with the following dilemma: if the payers think it is research, they may not cover it. Indeed studies of treatments which are already standard clinical practice might be more analogous to Phase IV (i.e., postmarketing) clinical trials than to Phase III (i.e., effectiveness) clinical trials. This tautological problem within outcomes research may be solved in various ways, depending on the resources available to the institution. For example, some institutions may opt for internal funding of clinical work being investigated, thereby not seeking reimbursement for clinical services. Others may opt for the pre–post one-group design which may only require collecting data from patients during standard clinic visits. Others may hire independent private organizations to manage the data collection effort so that the apparent investigators are not obviously linked to the clinical facility. Whatever the solution, it will be advantageous for the clinical investigator to consider this tautological problem before initiating any research study.

Table 2 Feasible clinical health psychology research study designs: research questions and assumptions.

Study design	*Research question*	*Assumption*
a. Standard randomized controlled trial	Is treatment A better than treatment B on x outcome(s)?	Patients will accept randomization to a control group; randomization takes care of pretreatment group differences
b. Randomized consent	Is treatment A better than treatment B on x outcome(s)?	Patients will be likely to accept the treatment to which they have been randomized
c. Three-arm crossover	*i.* Is treatment A better than treatment B on x outcome(s)? *ii.* Does duration of treatment influence outcome(s)?	Washout period duration is known
d. Case–control	Is treatment A better than treatment B on x outcome(s)?	Groups are matched on relevant sociodemographic and medical variables
e. Solomon four-group pre–post	Is treatment A better than treatment B on x outcome(s)? Does measurement cue patients about salience and thereby influence treatment outcomes?	All groups are similar at baseline on outcome variables
f. Pre–post one-group	What factors are associated with better outcome(s) of treatment A?	Relevant factors are measured

8.05.2.4.2 Incentives of capitated care

Since health care becomes increasingly controlled by managed care, the incentives of this system must be considered by clinical investigators. The idea behind capitated care is that the provider is paid in advance for all medical care on a per patient (i.e., capitated) basis. Unlike the fee-for-service arrangement where the incentive is to provide more medical services, capitated care presents an incentive to minimize the medical services provided so that the cost per patient is reduced.

Given this incentive structure, research which seeks to evaluate adjunctive treatments such as behavioral medicine interventions may face additional barriers. Such programs may reduce unnecessary medical care use in the future by attending to current psychological morbidities. These morbidities can lead to increased healthcare utilization (Browne, Aprin, Corey, Fitch, & Gafini, 1990), but treating them with adjunctive behavioral interventions might lead to a cost offset in the longer term (Friedman, Sobel, Myers, Candill, & Benson, 1995). However, managed care providers may be focused on short-term savings, while psychological interventions may appear to increase rather than reduce healthcare costs. Investigators may need to consider that short-term increases in utilization may appear to work against the incentives of the system. Consequently short- and long-term costs and outcomes should be addressed in clinical research studies.

8.05.2.4.3 Legal considerations

Although informed consent has become an assumed step in any research process, there are still legal issues which may arise due to an increasingly fearful and litigious culture. Legal issues may play a larger role as clinical investigators are required to seek consultations from medical attorneys rather than focusing on the best research design to ask the research question. A real-life example of such a situation was one where researchers sought to evaluate the predictive value of inability to answer a standard quality-of-life questionnaire, the SF-36 (Ware, Snow, Kosinski, & Gandek, 1993). Their original design was a standard case–control design which followed elderly patients in a primary care setting. Eligible participants were to be those patients who were unable to complete the questionnaire without missing data. Half of the patients were to be observed without additional intervention, and half were to be telephoned monthly by a clinical nurse to ensure that they adhered to treatment regimens and/or saw a physician if needed. After consulting with lawyers, however, the investigators were informed that such a design put the clinic at risk of malpractice: if one of the control patients died and a relative learned that the patient had participated in this study, the relative might sue the clinic for withholding treatment even though the efficacy of the treatment was exactly the focus of the investigation. The researchers were advised to change their design so that half the patients got a pre- and post-test along with the telephone intervention. The other half provided data only at the post-test. Clearly such a design limited the investigators" ability to adjust statistically for baseline health status. However, the fear of possible litigation over an unproven treatment dominated the design selection. Future clinical investigators might be wise to consider the legal perspective, and to ensure informed consent so that scientific rigor does not lose priority to litigious concerns.

8.05.2.4.4 Unavoidable costs of doing research

No matter how much a clinical research study attempts to dovetail with standard clinical care, there are some costs which cannot be ignored. For a study to be rigorous and to maintain a reasonable response rate, some staff time will need to be devoted to the initial training as well as for implementing the Total Design Method (Dillman, 1978). Further, it may be necessary to pay for some of the clinicians' time for aspects of the research which do not strictly involve delivering clinical care. For example, some time will be needed for occasional meetings to confirm that the study procedures are clear and implemented correctly, for interpreting results of the data analysis, and for completing manuscript preparation for peer review. Finally, for studies implemented by mail or by telephone there will be costs associated with pretesting instruments, printing, postage, and telephone follow-up. Although these costs are minimal, there are necessary components of the research endeavor and should be considered before beginning the study.

8.05.2.4.5 Ethical considerations

The integration into any research endeavor of review by the appropriate committee for the protection of human subjects and informed consent have become crucial steps for maintaining ethically sound research. Nonetheless, some ethical concerns may be raised which are beyond the scope of such processes, especially as research efforts seek to extend clinical service evaluations to lower income patient populations. One example would be research which seeks to evaluate differences in clinical effectiveness of a behavioral medicine intervention on higher vs. lower income patients. Although standard informed consent procedures might list the risks and benefits of such benign interventions, they would be unlikely to highlight the impact of treatment termination. When the referent patient population is unlikely to be able to afford continuing the treatment after the study ends, it is incumbent upon the investigator to make the implications of treatment termination explicit. Further, the investigator may need to provide access to social service providers who can direct outreach after study termination and identify resources which would be otherwise unavailable to patients. Such considerations may not be apparent in the initial review by the committee for the protection of human subjects and may arise in the course of co-investigator meetings to clarify study procedures.

8.05.2.5 An Emerging Theoretical Challenge for Outcomes Research

An emerging area of interest and work by researchers from a broad range of disciplines is focused on understanding "response shift phenomenon." This term refers to the idea that individuals facing a significant health challenge may experience a change in internal standards, values and the meaning of quality of life (Breetvelt and VanDam, 1991; Schwartz & Sprangers, under review; Sprangers 1988, 1996; Sprangers et al., 1995; Sprangers, Rogemuller, VanDen Berk, Bowen, & VanDam, 1994). As both Heraclitus and Alphonse Karr noted long ago, change is a constant in life; yet there is an underlying and undeniable structure to personality (Funder & Colvin, 1991). Quality-of-life investigators have documented a type of inconsistency in self-reported health outcomes which is likely to have important implications for evaluating the impact of cognitively-based interventions.

Acute health-state changes may have an impact on psychological morbidity, followed by accommodation and adaptation to the functional limitations imposed by the illness. This shift explains how an individual's life satisfaction may not be directly related to their functional status. Bach and Tilton (1994) found, for example, that individuals with tetraplegia who were dependent on a ventilator reported higher life satisfaction than tetraplegics who were able to breathe independently. Individuals facing a significant health challenge may scale down their expectations of health, may be more appreciative of the social resources which support their daily living activities, and may be making significant adjustments in the importance of life domains (Bach & Tilton, 1994).

These individual values may also play an important role in determining the complex inter-relationships underlying quality of life. For example, satisfaction with one's functional status has been found to be related to psychological well-being only among those individuals who viewed the abilities being evaluated as very important (Blalock, B. M. DeVellis, R. F. DeVellis, & Santer 1993). Interventions which improve social support may affect patient values, priorities, and appreciation of the resources they have (Norman & Parker, 1996). These social support interventions may allow them to maximize their quality of life despite important physical setbacks. Thus, it may be hard to differentiate change due to active interventions and truly improved functional status from change due to patient accommodation to level of function.

Response shift represents a challenge to health researchers. It lies under the surface of measurement, camouflaged by an apparent lack of change in treatment outcomes. Intra-individual shifts in referents and priorities may mediate both well-being and functional status (Sprangers & Schwartz, under review). Understanding the predictive significance of this intra-individual variability is at the heart of meaningful outcomes measurement, and has the potential to lead to a paradigm shift in the many fields of investigation that rely on patient self-report.

8.05.3 SUMMARY

This chapter reviewed various design issues which might facilitate implementing health psychology intervention research in an active clinical setting. Key considerations were described to improve the ability to detect treatment effects, and several research design options were presented to highlight how one's assumptions and research questions determine the optimal research design. Finally, response shift phenomenon was discussed to emphasize how internal standards, values, and an individual's concept of quality of life can be a dynamic process which is under the surface of current measurement techniques. This emerging construct should be considered in future clinical health psychology research, so that the full impact of interventions is more likely to be revealed in clinical research.

ACKNOWLEDGMENTS

The author would like to thank Elissa Laitin for her assistance in manuscript preparation. The project was supported by grant number R01 HS08582-01A1 from the agency for Health Care Policy and Research to Dr. Schwartz.

8.06.1 INTRODUCTION

In the future,

> In the health care arena, psychologists will function less within an independent (autonomous) practice model and more within organised health care settings (Pion, 1991). The emphasis within these organisational frameworks will be on an interdisciplinary, collaborative model with other health care professionals in which psychologists will have shared responsibility and decision-making for patient care. (Siegel, 1995, p. 342)

The development of new health technologies and health care providers in the developed countries is leading to an enlarging "health industry." The way in which health services are organized is changing rapidly and profoundly on both sides of the Atlantic. These developments provide increased opportunities for professionals concerned with health issues, and also create a need for health professionals to examine their role and contribution. Several innovations demand expertise in both measuring and improving behavioral and psychological processes (Johnston & Weinman, 1995). For example, the growing emphasis in health care on the prevention of disease has led to a need for professional skills relevant to understanding and altering health-related cognitions and behaviors. The increased prevalence of chronic rather than acute disease has created a need for the understanding of emotional responses and problem-solving coping skills, in addition to existing biomedical knowledge. Changes in the structure of the health services in the 1990s has increased the need to evaluate the impact of these services on the users.

In the UK, the control and direction of health care services have moved from practitioner to purchaser, and from clinicians to general managers and accountants. This poses the challenge of whether health care professionals can adapt to these changes and whether they can influence the changes to achieve their objective of improving the health and well-being of the population or of sections of the population. This chapter describes the emergence and skills of clinical health psychologists, the consultancy role and the stages it involves, its possibilities and constraints and the responsibilities of psychologists in promoting themselves and their disciplines to existing and potential consultees. Whilst many of the examples are from the UK, the issues raised are of more general relevance.

8.06.1.1 Clinical Health Psychology

Health psychologists have much to contribute to the prevention and management of problems within organizations, and have the skills to function in a variety of settings (Altman & Cahn, 1983). The essence of training in psychology is learning about the factors that affect the causes, maintenance, and changes of human functioning at the individual, group, and organizational levels. Human functioning is considered in its component parts (behavior, thinking, and emotion) and an analysis is made of the relationships between these components, and of the relationships between these components and situational factors. Health psychology is a broad discipline: for convenience, content areas have been summarized into five broad areas (Johnston & Weinman, 1995).

(i) *Health risk behaviours*. The nature, causes, and health effects of such behaviors as smoking, substance abuse, unsafe sexual behavior, and harmful dietary choice; the role of stress and dispositional factors in the etiology and exacerbation of disease; psychological theories and interventions for primary prevention and health-related behavior change in community and workplace settings.

(ii) *Health protective or enhancing behaviors*. The uptake and maintenance of such behaviors as exercise, healthy dietary choice, teethbrushing, health checks/self-examination, and attendance for preventive medical screening; psychological approaches to health promotion.

(iii) *Health-related cognitions*. Cognitive processes that mediate and determine health and illness behaviors. These include general health beliefs/attitudes; attributions, control, and self-efficacy beliefs; symptom perception; and illness representations in children and adults. There are a range of theoretical models and frameworks that can be used, not only for explanation and prediction, but also for developing interventions (e.g. to modify health beliefs, increase internal control, or self-efficacy beliefs).

(iv) *Processes influencing health care delivery*. The nature and effects of communication between health care practitioners and patients; patient satisfaction and adherence to treatment and advice; the uptake and response to preventive services such as screening; stressful medical investigations and treatment; hospitalization; health care staff attitudes; decision-making, work stress; quality assurance; measurement issues in audit and outcome evaluation; psychological interventions to improve communication, facilitate adherence, and prepare for stressful medical procedures.

(v) *Psychological aspects of illness*. The psychological impact of acute and chronic illness on individuals and their families and carers across the lifespan; pain behavior and rehabilitation and health-related behavior change; dying, death, and bereavement. Psychological intervention to promote self-management, facilitate coping with pain or illness, to improve quality of life, and to reduce disability and handicap.

In all these areas, a wide range of skills is used, including assessment, evaluation, communication, teaching, and intervention. The work of a health psychologist is targeted at the problems of public health, the provision of health care and the response to illness. The problems may be identified by health care agencies, health professions, and organizations and employers outside the health care system. Psychologists can bring a systems approach to problems and locate them and the health care system within their wider contexts. By putting these skills together, psychologists are able to address “what if” questions by developing theoretical and quantitative causal models of behavioral predictors.

Health psychology is a new discipline. The first book including the term “health psychology” in its name was published in 1979 (Stone, Cohen, & Adler, 1979). Health psychology is defined as the study of psychological and behavioral processes in health, illness and health care (Johnston, 1994). Clinical health psychology has been used to refer to clinical, organizational, or health psychology in a health-service setting. There are two primary reasons for interest in the contribution of clinical health psychology to other health professionals and to health service managers (Jansen, Methorst, & Kerkhof, 1991). The first is the increasing recognition that solutions to health problems may be found by seeking behavioral solutions (e.g., risk-factor management in the case of heart disease). The second is the escalating cost of health care, which fosters a welcoming of prevention and of interventions that reduce reliance on the medical system (e.g., psychological interventions for chronic pain management).

Clinical health psychology aims to translate research into practical applications that can help people lead healthier lives. This may take several routes: teaching and training health professionals and patients; working with patients to adopt healthier lifestyles or to manage problems such as pain or stress; and consulting with professionals about patient, staff, or organizational issues. Many research findings are not applied and do not influence clinical practice or policy, a situation that is itself the subject of analysis and study by health psychologists (Marteau, Sowden, & Armstrong, submitted).

The knowledge bases required for a successful health psychology consultancy role are theoretical models, (see Chapter 8.01, this volume) measurement techniques (see Chapter 8.04, this volume) successful interventions, factors that influence behavior and behavior change (a portfolio of examples that is currently being collected by the British Psychology Society Special Group is cited here), and specific health psychology knowledge (e.g., psychophysiological processes, health behavior, stress, communication and decision-making in health care, consequences of and coping with illness) (see Chapters 8.02 and 8.07, this volume).

8.06.1.2 What is Consultancy?

The term “consultation” refers to one party (individual, committee, or organization) formally seeking the advice of another. The consultee poses the initial questions and the consultant shapes them, proposes a methodology, implements it, and reports back. Health psychology consultancy is the use of these psychological skills and knowledge to facilitate, develop, or enhance the effectiveness of others in the maintenance and improvement of human health.

Consultancy has the potential to influence large groups of people and to change processes that depend on many and varied people and organizational policies, procedures and practices. As with other health services, consultancy must be evidence based, and not just taken on trust. In this age of squeezed resources for health care, consultancy must be shown to be effective and cost-effective. This requires making the consultancy component of health psychology explicit and embedding it within a research framework.

In order to expand their role to include consultancy, psychologists need to apply the skills and knowledge acquired in working with individual problems to working with organizational and service problems (Michie, 1993). Areas in which psychologists have expertize relevant to consultancy work include:

(i) understanding the contextual nature of health problems;

(ii) the systematic analysis of problems and potential solutions;

(iii) the understanding of change processes that enable recommendations about the best ways of achieving the task or goal identified by the consultee; and

(iv) research skills that enable the evaluation of services, interventions, and changes.

8.06.1.3 Issues for Consultancy

The main issues for clinical health psychology consultancy are:

(i) Patients: improving care and decreasing patient anxiety.

(ii) Staff: risk assessment, reducing stress, reducing ill-health, and increasing job satisfaction.

(iii) Improving communication: between staff and between staff and patients.

(iv) Assessing need for services.

(v) Service evaluation, quality assurance, and audit.

8.06.1.4 A Systemic Approach

A systems framework for health is described well by Stone (1979, 1982). A system is a set of elements related to each other in such a way that the actions of one element affect the states of, and initiate or modify activity in, other elements of the system. A goal of health psychology is described as discerning the relationships between health activities and the entities that appear in the activities. The health system is seen as being much broader than the health care system, including entities such as environmental health hazards and health resources, public health measures and planning agencies, health education, and political behavior.

The health care system is composed of people, organizations, and machines that protect, enhance, or restore health. The people may be users, providers, family members, policy-makers, educators, or researchers. The organizations are any collections of individuals who act together to promote good health (e.g. community organizations, hospitals, or government departments). The machines are usually computers. The broader world of health hazards includes toxins, pathogens, stressors, and safety hazards such as defects in tools or materials. Health resources include knowledge and technical skills, leisure, recreation and health care facilities, material commodities such as housing and money, tools and machines, and regulations, laws, and procedures.

Health psychologists seek to understand the system in which, or with which, they are working, in order to develop ideas about how it could be improved and to intervene to change it, if necessary. Their contribution lies both in communication skills to gain the agreement of relevant people that change is desirable and in developing strategies to achieve the desired changes. Other skills that psychologists have are the ability to make predictions about the effects of change in particular areas, to test those predictions, and to interpret the results within a theoretical framework. These are all skills that are required in organizational consultancy.

The work of health psychologists has been described as lying on a dimension, extending from basic research to the design and development of new interventions, to the implementation of interventions in controlled trials, to the evaluation of programs of service delivery (Stone, 1982).

Organizations have certain tasks to perform, and patterns of behavior and beliefs about the organization develop around the performance of these tasks. Consultants describe and examine patterns of beliefs and behavior around specific tasks and the effect of these patterns on relationships and communication throughout the organization (Campbell, Draper, & Huffington, 1989). Observing, understanding, and developing hypotheses about the way in which these patterns or routines protect certain relationships are key to enabling organizations to change. Organizations change when people's perceptions, beliefs, and behavior change. This can be achieved by systemic interviewing, feedback within the organization, and targeted interventions. Systemic interviewing involves asking about the way in which people think, the way in which their beliefs affect their actions and relationships in such a way that challenges discrepancies between beliefs and actions.

8.06.1.5 Who are the Consultees?

Consultees are individuals, groups, or organizations that enter into a negotiated contract with the consultant, agreeing the objectives, process, and conditions of the organizational consultancy work. They may be those directly providing services, both medical and nonmedical, they may be those planning and managing these services, or they may be those purchasing services (see Figure 1). Most would not think of psychologists as the appropriate professionals to help them. However, the problems that they face are often ones of behavior and of behavior change. Management problems in audit and evaluation, in implementing policies and guidelines, and in developing and maintaining teams are examples of this.

In the UK, about 40% of health psychologists are employed by health services, either to help develop and evaluate services to patients or to deal with general problems of quality assurance, preventive health care, intervention at an organizational level, or to assist in setting and evaluating targets for health care. Examples of psychologists providing consultancy in the UK health service can be found in *The change directory: Key issues in organisational development and the management of change* (Brunning, Cole, & Huffington, 1990) and *Internal consultation in health care settings* (Bor & Miller, 1991). Similar work in other areas of the educational and social services is described in *Internal consultancy in the public sector: Case studies* (Huffington & Brunning, 1994).

In the USA, business and industry pay for more than 25% of the nation's health care costs, giving employers a direct financial interest in developing health promotion programs. In response to this, occupational health psychology has developed a "systems consultation" model (as described above) to help managers identify employees' needs, to meet these needs with appropriate forms of intervention, to communicate effectively these needs and expectations to the individuals responsible for the development of health promotion programs, and to ensure that managers' expectations of success are reasonable and in line with current capabilities and resources (Everly, 1986).

8.06.2 WHAT DOES CONSULTANCY INVOLVE

There are five stages to consultancy: the approach from the consultee, refining the question, developing the methodology, implementing the methods, and reporting back. Although these stages are sequential in principle, there is a flexibility in practice, with overlapping activities and revisiting of earlier stages as the work develops. Practical examples of these stages are given in Section 8.06.6.

The approach from the consultee involves the following:

(i) being clear about who is the consultee (e.g., manager, clinician), what the initial questions are, why the questions are being asked, what the problem is that needs solving, (e.g., lack of resources, interpersonal conflict, the consultee's anxiety);

(ii) discovering what answers the consultee is seeking (e.g. literature review, descriptive research, an intervention); and

(iii) establishing the nature of the approach (e.g. an informal contact, a formal research initiative, a direct approach for consultancy).

Refining the question requires:

(i) an analysis of the situation presented by the consultee and the formulation of problems such that they are specific and testable, with clear operationalized objectives;

(ii) acquiring relevant background information (e.g., understanding formal and informal systems of communication within the organization, knowing who are the key individuals and committees with power and influence, and anticipating potential barriers to consultancy work within the organization).

(iii) defining the proposed product of the consultation (e.g., a literature review, a psychological opinion, a new procedure, a descriptive study, a study of factors associated with, antecedent to or consequences of an event or phenomenon, an evaluation of the consultee's intervention, an evaluated psychological intervention, which may be new or an adaptation of an intervention from elsewhere or from research literature); and

(iv) the ability to win consent for evaluation at an early stage of the consultation, including developing a baseline.

Developing the methodology requires:

(i) A methodology that allows the generation of specific answers to specific questions. This may involve a systematic literature review (Chalmers & Altman, 1995), qualitative methodology (Smith, Harre, & Langenhove, 1995), or research designs for descriptive studies (see Chapter 5, this volume).

(ii) The use of valid and reliable measures to determine whether objectives have been achieved and to test any research questions within the consultation (see Chapter 8.04, this volume). This will require knowledge of the relevant research literature, and an ability to use databases and to design and pilot measures where appropriate ones do not already exist. A comprehensive range of current psychometric measures are given in *Measures in health psychology: A user's portfolio* (Johnston, Weinman, & Wright, 1995).

(iii) The ability to include a simple economic evaluation.

(iv) Strategic thinking (e.g., anticipating hurdles and barriers and developing plans for overcoming these, planning for any anticipated adverse consequences).

(v) Negotiating access to resources and winning agreement from all necessary individuals, groups, and departments.

(vi) Identifying the blocking and facilitating forces within the organization.

(vii) Negotiating access to all information sources, and identifying relevant gatekeepers and those who must give approval.

(viii) Setting agreed boundaries (e.g., confidentiality issues, time constraints, starting and finishing dates, review dates, location, report writing and publications).

Implementing the methods requires:

(i) Achieving the understanding and consent of the consultee and other relevant individuals, groups, and departments. This involves a sensitivity to the consultee's agenda, both explicit and hidden, and to potential threats posed by the consultancy process.

(ii) Involving the appropriate individuals and groups in the relevant aspects of the process (e.g., student health professionals in data collection).

(iii) Assigning clear roles and responsibilities to those involved, including the consultant and the consultee, and a clear statement of these to the relevant people.

(iv) Appropriate and accurate data collection, analysis, and interpretation.

(v) The maintenance of a professional role.

(vi) Drawing up a written contract of the objectives, process, and conditions of the consultancy work, and defining the resources required for all stages of the consultancy process.

(vii) Clear communication and effective meetings.

Reporting back requires:

(i) The ability to give feedback to the consultee and other relevant audiences in appropriate ways such that maximum effect is achieved.

(ii) Clear and realistic recommendations.

(iii) Negotiating where to publish and present the results and who the authors should be.

Outlets may include those relevant to the consultee's discipline, to health psychology, or to multidisciplinary audiences.

(iv) Dissemination of results, including both informal and formal written reports, and verbal presentations.

8.06.3 EVIDENCE-BASED CONSULTANCY

If the consultancy process is to be evaluated, its objectives must be defined and measurable. This is impossible in situations in which the consultancy role adopted by health psychologists is not made explicit. The outcome criteria used in evaluations may be very varied (e.g., staff or patient satisfaction, financial savings, and adherence to guidelines). Many consultees do not appreciate the importance of a scientific approach to service evaluation, including the evaluation of consultancy work. Psychologists need to introduce the importance of well-designed and conducted evaluation at every opportunity in their contact with other health professionals.

Psychologists have an important role in defining the outcomes used in evaluation. Instead of using a biomedical disease model, in which signs and symptoms are reflections of tissue pathology and patient reports are often discounted, psychologists use a behavioral model. The important indicators of health and well-being are seen as behavioral-overt behavior, cognitions, and emotions. Outcome measures in health and medicine should therefore be anchored in their relationships with behavior (Kaplan, 1994), and psychologists are the obvious professionals with expertise in this area.

8.06.4 OPPORTUNITIES FOR PSYCHOLOGY CONSULTANCY

There has been a fear among UK psychologists that they could become marginalized by health service changes (Ovretveit, Brunning, & Huffington, 1992). This situation has been mirrored in Australia:

> Lack of knowledge about the consequences of organisational change resulting from restructuring, and exclusion from a strategic influence in the process of change, makes allied health professions vulnerable to a substantial reversal of both power and prospects. (Boyce, 1991)

Alongside the possible intended benefits of health service re-organization are possible problems for staff and for health care organizations. Staff may become anxious or demoralized by uncertainty and by change, with the consequence that they work less effectively, with more absenteeism and less job satisfaction. Services may suffer if staff have less motivation, time, and energy to develop services and to improve their quality. The organization may become less effective and efficient if apathy, poor communication, and conflicts between individuals, teams, and departments develop. However, organizational changes are a potential opportunity, as well as a threat. The very problems that may be produced by the changes and the tasks faced by those trying to manage the changes give the potential for a new role for psychologists, that of organizational consultant. Psychologists are the group of health professionals seen as having skills and knowledge relevant to the process of change.

The importance of understanding the role of broader forces within society has been emphasized in a volume considering the international development of health psychology (Jansen & Weinman, 1991). The future shape of health psychology will be influenced both by the needs of society and developments within medicine, and by pressures within the discipline. In order for psychologists to understand the ways in which social conditions affect health and health-related behavior, they need to understand and collaborate with a variety of other disciplines (e.g., epidemiology and researchers of consumer behavior).

As health psychology is a relatively new discipline, jobs and consultancy contracts will often have to be created. It is not enough for health psychologists to have skills relevant to situations in which they have no widely recognized track record. They will have to define the job tasks, clarify the skills needed, and demonstrate to potential employers that their skills and orientation will make a contribution (Altman & Cahn, 1987). To a large extent, health psychologists will have to create their own job market. This will require an understanding of, and an ability to engage with, what potential employers want. A survey of potential employers of applied psychologists in the USA in 1979 found that the most important skills sought were the ability to communicate, interview, conduct impact evaluations, plan human resources, use statistics, and have knowledge of the particular area (Edwards & Holmgren, 1979). In a qualitative study of the future organization of six therapy services in the UK, Ovretveit (1992) summarized some of the elements needed for their consultancy role: to know how the health service market works, to attend to what purchasers want, and to judge how they may be persuaded to finance the service. He advised the development of strategic plans, which should include an analysis of the "business environment," a rationale for developing activities, the resources needed (people, capital, and revenue), and the end points to be reached (strategic objectives and a business plan).

Psychologists have a well-established role of providing psychological services directly to patients. They are also known for the research they conduct. The consultancy role is less associated with psychologists. In the UK, health psychologists are becoming increasingly aware that this is a role that is already being played, and one that could be developed with good effect for the quality of services, for multidisciplinary work and for the spread of psychological knowledge and skills. The potential for consultancy work by psychologists is much greater than is currently demonstrated and recognized. The realization of this potential will partly depend on the willingness of psychologists and the profession to develop their consulting role (Ovretveit et al., 1992).

A broader perspective for translating research findings into effective practical programs has been taken by Mary Jansen and colleagues in the USA (Jansen, Methorst, & Kerkhof, 1991). As well as having a knowledge of health care systems, psychologists should be familiar with media techniques to promote their messages and their work and thereby play a greater role in the political process. Cynthia Belar (1995) makes the point that health psychology is not just clinical psychology in a medical setting, citing examples of health psychologists being consulted by a government on noise abatement, designing advertising campaigns to increase the use of safety belts, and being consulted by schools about smoking prevention.

National and local governments are seen as ideal employers of health psychologists since they regulate health service delivery and costs, formulate laws to regulate health behavior (e.g., drink driving), and regulate public health activities affecting the environment (e.g., the Clean Air Act). Potential positions for health psychologists have been identified as:

> working with legislative committees specialising in health issues (e.g., House and Senate subcommittees), executive agencies and administrative departments (e.g., Health Care Financing Administration, National Institutes of Health, National Institute of Mental Health, and Environmental Protection Agency), government research organizations (e.g., Congressional Research Service, General Accounting Office, and Office of Technology Assessment), special bodies empowered to help control health costs and quality (e.g., health systems review bodies, professional review organizations), trade associations, and lobbyists who provide government officials with information. (Altman & Cahn, 1987, p. 238)

Psychology has the potential to be an influential partner in the development and management of health care resources and systems, but only if it widens its role. Elliott and Shewchuk (1995) state that:

> For this change to occur, psychologists must assume a more visible profile in lobbying at local, state and national tiers to ensure that behavioural health issues are included in policy formation, research agenda and the allocation of services. If professional psychology fails to assume this responsibility and meet this challenge, the profession risks being marginalised as a stake holder in the health care system. (p. 346)

In some cases, targeted outcomes and intervention may be more appropriate and effective at the level of society and community rather than at the clinic and organization level. There needs, however, to be clarity about the role being played by psychologists in different situations. Lobbying, campaigning, advocating, and influencing those with political power are political activities and may be very appropriate for the objectives of health psychologists. On the other hand, consultees need to be confident that consultancy work will be carried out within a neutral, rather than a political, perspective. Having said this, it is doubtful that neutrality can ever be achieved, and a better approach may be to be explicit about one's beliefs about issues relevant to the consultancy work.

8.06.5 PROMOTING THE CONSULTANCY ROLE

Much consultancy by applied psychologists goes on outside a formally contracted arrangement, which means that it may not be recognized, either by the consultee or the consultant. In order to help develop this area of work, psychologists should be encouraged to formalize and evaluate the consultancy work they carry out and to publish the results. Psychologists need first to establish what potential employers want, which can often be done by obtaining their annual reports, strategic plans, and other relevant documents. The next step is to convince them that they have the expertise to meet their needs, to achieve agreed tasks within the time and cost constraints, and that their track records are reasons for the employer to choose them. What hinders many psychologists is not their lack of skill but their lack of focus on what they can deliver, and their diffidence in persuading others that they have something to offer of a quality that cannot be obtained from others.

The point is well made if the term "health psychology" is substituted for "your company" in the following statement, cited in Altman and Cahn (1987):

> I don't know who you are.
> I don't know your company.
> I don't know your company's product.
> I don't know what your company stands for.
> I don't know your company's customers.
> I don't know your company's record.
> I don't know your company's reputation.
> Now—what is it you wanted to sell me?

One way to promote psychologists as consultants to potential purchasers would be for psychological professional associations to collect case studies of successful consultancy work. Producing an informative and attractive summary of the consultancy services on offer, in leaflet, video, or internet homepage form, is essential. Purchasers should be encouraged to write consultancy into the service contracts and job descriptions of psychologists. The training of consultancy skills should be included in postgraduate courses of applied psychology and as part of continuing professional development

8.06.6 EXAMPLES OF CONSULTANCY WORK

Examples of specific questions raised with a clinical health psychologist providing a consultancy service to UK health care organizations are listed below (taken from Michie, 1993, and Earl L., 1997, personal communication).

(i) Questions from managers:

(a) Hospital

What will the effects be on staff and patients of decentralizing our outpatient service into clinic-based teams?

How can we develop an integrated oncology service from the present divided service?

What are the reasons for the very high absenteeism on a particular ward and what recommendations would you make to improve the situation?

How can we best assess patient satisfaction with our services?

Is a new receptionist skills training program effective in changing staff behavior and in improving patient satisfaction with their reception within the hospital?

(b) Community

What are the problems for the various staff groups in introducing parent-held health records and how could they be overcome?

What are the effects of changing health visitors' work from individual to "corporate" caseloads?

What can be done to improve the communication and integration of work between community-based nurses and nurses working in doctor-led primary care teams?

(ii) Questions from clinicians:

Is the way in which we advise patients with diabetes about its management contributing to the worryingly high rate of eating disorders we are finding?

Can we do something to reduce the very high anxiety in women referred with suspected breast cancer at their first hospital appointment?

Is the arthroscopy patient information booklet and video helpful and, if so, how?

Is the oncology counseling service effective?

(iii) Questions from purchasers:

(a) Health authority

What are the dimensions of quality of health care valued by the local population and are they sufficiently represented in our contracts with provider units?

What are the priorities of maternity service users and how far do current services meet changing childbirth national guidelines?

(b) Multiagency:

What is the current service provision for children who have been sexually abused, the perpetrators, and nonabusing carers?

What are the gaps in service and recommendations for resource allocation?

Although there are many examples of work such as this, there is a paucity of consultancy work published in peer-reviewed journals. This limits the possibility of others learning from and building on the work and limits the promotion of psychologists as competent and experienced in carrying out this type of work. One example of published consultancy work comes from a health psychology unit based in the medical school of a London teaching hospital. This unit was set up in the late 1980s by Professor Marie Johnston to integrate clinical, organizational, and health services research work. In carrying out consultancy work, the team sought to include psychological questions within the projects undertaken and to ensure that the work was designed in such a way that it would be of publishable standard.

Consultancy projects were primarily in two areas: developing and evaluating written material for patients, and the health and well-being of health professionals. Some examples are described below. This is followed by a description of consultancy work carried out within a Health Promotion Unit by a UK psychologist, Barbara Wren.

8.06.6.1 Developing and Evaluating Written Material for Patients

One of the interests of this group was the effect of written information on patient outcome. Clinicians in several specialities were aware of the problem of high anxiety in patients referred for investigation and approached the health psychology unit for help. Several studies were carried out and the results were reported both to the appropriate parts of the commissioning organization and to the wider research community, the latter being in the form of publications and conference presentations.

8.06.6.1.1 The breast clinic

The consultant breast surgeon was concerned by his clinical experience of very high levels of anxiety shown by women attending a breast outpatient clinic for the first time, and approached the health psychology unit for advice as to how this might be prevented or reduced. The first contribution of the health psychologists was their knowledge of previous relevant research. This had suggested that written information may improve patients' feeling of well-being and make them feel better informed and less worried (Eardly, 1988; Hutchcroft, Snodgrass, Troyan, & Wares, 1984; Wallace, 1984). On the basis of this, a booklet aimed at addressing procedural worries by giving information and coping advice was designed and given to women within a randomized controlled trial (Madden, Johnston, & Parbhoo, 1994). This study confirmed the clinical observation that this group of patients was highly anxious, and also found that their most dominant worry was more often about the outcome of their appointment rather than about the procedure. Although the booklet increased women's knowledge, it did not reduce their anxiety. These results led to a subsequent study comparing three kinds of preparatory information: that dealing with clinic procedures, that dealing with the outcome of breast problems, and that designed to increase perceived control (Michie, Rosebert, Heaversedge, Madden, & Parbhoo, 1996). Women receiving information were found to be less anxious than the control group and perceived their problem as less serious. There was one difference between the types of information booklet: those receiving coping or outcome information were less worried about what the doctor might find than those receiving procedural or no information.

8.06.6.1.2 The colposcopy clinic

Another group of patients reported by clinicians at this hospital to be highly anxious was women referred for colposcopy following an abnormal cervical smear result. The effectiveness of two booklets, one produced nationally and the other designed locally to be simpler and shorter, was evaluated in a randomized controlled study (Marteau, Kidd, Cuddeford, & Walker, 1996). Although both booklets led to increased knowledge, only the simpler one reduced anxiety. In addition to using simpler language, the shorter booklet also contained information about coping strategies and was associated with the clinic that the women were attending. It was recommended to the clinic that they use this booklet.

8.06.6.1.3 The rehabilitation department

A different use of written information was used in response to a request by the hospital's physiotherapy department to help recovery during rehabilitation. A previous study had found that patients with a higher level of perceived control over recovery made more progress with recovery from disability than did those with a lower level of perceived control (Partridge & Johnston, 1989). A simple intervention was designed with the aim of increasing patients' sense of control over their recovery (Johnston, Gilbert, Partridge, & Collins, 1992). Using a randomized controlled design, patients were sent an appointment letter with additional paragraphs under the heading "Information sheet for patients receiving physiotherapy." Patients receiving this letter were found to have higher levels of perceived control and tended to be more satisfied with information than did those who received the standard letter. The extended letter was therefore used routinely by the physiotherapy department.

8.06.6.2 The Health and Well-being of Health Professionals

The same health psychology unit was also approached to carry out various projects concerning staff health, since this was recognized as being important both in its own right and as a factor in delivering high-quality patient care.

8.06.6.2.1 Stress management

We were asked by the Director of Nursing and the General Manager of the hospital to assess stress levels amongst nurses, and found they reported greater problems in dealing with stress than the norm (Michie, Ridout, & Johnston, 1996). This was tackled in three ways: introducing stress management training courses, offering a counseling service based at the hospital's Occupational Health Unit, and running a health screening and advice program for staff.

Although the first two initiatives were not evaluated within a randomized controlled trial, comparison of scores before and after the interventions showed that there was lower anxiety and increased job satisfaction after the stress management training (Michie & Ridout, 1990). Six months after counseling, staff were less anxious and depressed, more satisfied with their work and life outside work, and perceived themselves to be functioning better at work compared to before counseling (Michie, 1992a, 1992b). There were fewer days and episodes of sickness absence in the six months following counseling compared with the equivalent period before counseling (Michie, 1996).

8.06.6.2.2 Health checks and feedback

The Occupational Health Unit of the hospital was interested in the possibility of staff health screening as a way of detecting and reducing potential health risk factors, including stress, and of promoting healthier behaviors. They approached the Health Psychology Unit, who suggested an evaluation that included the impact of two methods of giving screening results on health behavior and beliefs (Michie, Johnston, Cockcroft, Ellinghouse, & Gooch, 1995). A free health screening program was promoted throughout the hospital for 10 days before under the slogan "Good Health Campaign" by posters, letters to departmental heads, and advertisements in the local press. Screening sessions were held in the Staff Recreation Club twice a day for one week. Questionnaires were completed before the physical measurements and staff were given written results of these. Those found to have raised blood pressure or very high scores on the General Health Questionnaire were given a standard letter to take to their general practitioner. All the 297 staff attenders were contacted by post six months later and invited for a repeat assessment.

Staff attending the program were compared with a stratified sample of non-attenders. Attenders were allocated randomly to getting simple informational feedback of their results or to receiving feedback plus verbal and written advice, personal target setting, and a written contract. Those receiving this more extensive feedback were found to have lost more weight and increased their exercise more than those receiving simple feedback. This project is an example of including a psychological research question within a piece of consultancy work.

8.06.6.2.3 Stress in medical school

This research group was also consulted about concern expressed by the medical school about stress in their students. The importance of medical schools recognizing the problem of stress and taking steps to reduce it was emphasized by the British Medical Association (BMA, 1992). This report concluded that medical students should be taught stress management techniques. A stress management course was designed and evaluated by a health psychologist for students in their first clinical year, which is known to be particularly stressful (Michie & Sandhu, 1994). Questionnaires assessing mood, attitudes, and the causes of stress were given to all students at the beginning of the year and one year later. The course was offered four times a year, and students were allocated to a waiting list of about three months. This allowed students to act as their own controls in order to assess whether the courses had an impact. The courses ran for three weekly sessions and students were asked to complete questionnaires before and after the course. Whilst on the waiting list, the students had completed the same questionnaire at two time points with a similar intervening interval. The uptake of this optional course (which coincided with sports afternoon) was 17%. Compared to nonattenders, attenders were more anxious, less satisfied with themselves and their life, and perceived both their work and outside functioning to be poorer. Over the year, nonattenders became significantly more dissatisfied at work and increasingly perceived their functioning at work and outside to be poorer, whilst attenders showed no such deterioration over the year. Those who attended the course showed more improvement in reported work functioning after the course than when on the waiting list. These results showed that stress management was providing long-term protective effects as well as short-term benefits. The results were reported to the medical school, and the school subsequently agreed to fund an extra half day per week to continue this work. Without data to demonstrate that the intervention had a positive impact, it is unlikely that this piece of consultancy work would have led to long-term funding for the consultant.

The BMA is concerned about the problems of stress and long hours of work at all stages of the medical career. After a junior doctor died in the UK following excessively long hours of work, a health psychologist and a medical consultant known for their work in occupational health were approached to write an editorial in the *British Medical Journal* on the question of whether overwork can kill (Michie & Cockcroft, 1996). This required a structured literature search and the resulting article attracted worldwide attention, with many invitations to participate in conferences and media events.

If those being consulted do not have the necessary data to answer the consultee's question, or the means to acquire such data, a literature review (preferably systematic) may be the best method of response. An example of this is a review commissioned by a local health authority of interventions to promote contraceptive use and sexual health among young people (McAlpine, Abraham, & Davies, 1995).

8.06.6.2.4 Twelve-hour nursing shifts

As cost pressures on the health service have increased, various ways of reorganizing work have been attempted. One such change was the change in the length of working day among nurses from 8-hour shifts to 12-hour shifts. The health psychology unit was approached to evaluate this change, as described below (Johnston & Pollard, 1991).

(i) The approach from the consultee

The issue of introducing and evaluating 12-hour nursing shifts arose in the context of increasing efficiency in health services and was under discussion by national nursing bodies in the UK. It was raised in a multidisciplinary hospital management meeting. After some discussion, the meeting agreed that the director of nursing should obtain the assistance of the psychology department in evaluating the new shift system.

(ii) Refining the question

The question was refined to be a comparison of the 12-hour shifts with the more usual 8-hour shifts. As the new shifts were only being introduced on a limited set of wards, a comparison was possible. Attendance at meetings of the nursing group implementing the shifts made it clear that the nurses were concerned about stress and the possibility of poorer performance. Therefore the question was reformulated to: Do 12-hour shifts result in greater stress and poorer performance than 8-hour shifts?

(iii) Developing the methodology

Wards that were comparable in function and structure to the 12-hour shift wards were identified; for example, surgical admission wards were matched with surgical admission wards. Stress was conceptualized as perceived stress to be measured by self-report measures of stress, tiredness, and mood. Performance was assessed in terms of speed and error rates using computer-presented cognitive tasks that were already available in the hospital. Computer assessment was used to minimize a possible confounding bias of nurses' responses reflecting what they wanted management to believe, as may be more likely in self-report measures. The design was a matched comparison of assessments every four hours and at the beginning and end of each shift. There might be an effect with duration of the shift, so that the nurses on 12-hour shifts would, after eight hours, be comparable to eight hour shift nurses, or there might be cumulative effects of working 12-hour shifts so that nurses would show effects earlier in the shift.

(iv) Implementing the methods

The proposed methods were discussed and agreed with the implementation group and they helped to introduce the study to the relevant ward staff. With the assistance of other departments in the hospital, a computer was installed in the nursing office in each of the participating wards. A medical student doing his project work in psychology played a major part in collecting data, but additional assistance was obtained from other members of the health psychology unit. Initially, a member of the psychology unit was present to ask the nurses on each ward to complete questionnaires and computer tasks at the start and end of each shift and every four hours (throughout the 24 hours). This was gradually reduced to telephone-call prompts and beginning/end of shift attendance. Data were analyzed by the medical student and a member of the health psychology unit.

(v) Reporting back

The results of the study were reported directly to the nursing implementation group. Of particular interest was the finding that self-report stress measures showed no differences between the two shift patterns and that the differences observed occurred at the beginning of shifts on the computer performance tasks. Nursing management decided not to implement 12-hour shifts, largely due to the retirement of the nurse leading this change. The results of the work were presented at conferences and published (e.g., Johnston & Pollard, 1991).

8.06.6.3 Health Promotion in Primary Care

A recent coronary heart disease (CHD) prevention project involved establishing a health psychology post within a health promotion unit to support primary care teams in their CHD prevention activities. Consultancy requests were often made as a result of the consultee attending a skill-based training course run by the consultant, seeking further support for skills development. The development of a health psychology consultancy role within a health promotion setting enabled the sharing of skills and knowledge about health psychology, and also began the process of establishing a culture in which the importance of self and peer review became acknowledged. The model of health psychology that was developed linked a training and a consultancy role, as described below.

8.06.6.3.1 Individual lifestyle interventions in primary care

(i) The approach from the consultee

The consultee was a general practice nurse who, following attendance at a training course, requested help with planning the health promotion consultations that she was offering.

(ii) Refining the question

The meeting with the consultee was used to explore the reason for her request and to help her consider the specific areas on which she would like to focus. From this discussion it became clear that her concern was about the need for a framework and skills to plan and carry out health promotion interventions in primary care. The consultee felt that a counseling approach was not always appropriate, but was unclear about how else to structure consultations. Discussion indicated the need to clarify the approach the consultee was using at present and to offer support in developing new strategies if appropriate. The initial request for help was reformulated into the question: What framework is being used at present in individual health promotion consultations?

(iii) Developing the methodology

The consultant and consultee decided to audit 30 consecutive health promotion interventions. An audit form was developed that recorded the following information: demographic information, health information, and a record of the consultation and of any health promotion materials that were used. Health information was recorded in terms of CHD risk factors (i.e., body mass index, smoking status, units of alcohol, physical activity levels, blood pressure) to provide a profile of the health status of clients who were being offered health promotion. The health promotion intervention was recorded in an open-ended way to allow for as full a description as possible of the interaction between the patient and the practice nurse. The practice nurse was simply asked to write a description of the intervention with the client. Finally, a record of the health promotion materials used allowed us to look at the appropriateness of the information being provided and to consider alternatives if necessary.

(iv) Implementing the methods

The form was discussed and agreed with the consultee. During the period of collecting the data the health psychologist met twice with the consultee to review the use of the form and discuss any issues that it raised. This process helped to clarify the approaches that the consultee was using in health promotion consultations. It allowed for a focus on individual consultations and practical examples of the difficulties that the consultee was experiencing. Once data on 30 consultations had been collected the psychologist collated the information, drawing out the main themes and issues identified in the descriptions of the consultations.

(v) Reporting back

The results were fed back to the consultee. The data helped to identify the range of skills that she already had and was using with this group. It also gave a profile of the patients with whom she was working and allowed her to explore the difference between primary and secondary prevention in health promotion work. It provided an opportunity to discuss the different types of interventions being used (e.g. counseling and advice giving), to consider others (e.g., motivational interviewing techniques) and to discuss when each approach might be appropriate or inappropriate. It also allowed for a focus on the importance of assessing the client's health beliefs in order to develop responsive health promotion interventions. Finally, the consultee was able to identify further training and development needs, which she later pursued through the health promotion unit.

8.06.6.3.2 Group-based health promotion interventions in primary care

(i) The approach from the consultee

Two health visitors contacted the health promotion unit to ask for help with setting up a smoking cessation group. The health visitors worked with the CHD health promotion officer to set up a display and develop materials and leaflets to advertise and plan the course, which was targeted at new mothers. However, they were unable to recruit enough numbers for a viable group. It was decided to use the time that had been set aside for the group to meet with the health visitors and discuss how the identified client group could be worked within one-to-one consultations, as the client group did not seem to be accessible through group work. An initial consultancy session was offered, and four health visitors said they would like to attend.

(ii) Refining the questions

The session was facilitated by the health psychologist and the health promotion officer and focused on considering why it had been so difficult to recruit to the group. It emerged from this discussion that one of the difficulties had been the health visitors' own anxieties about raising the issue of smoking with clients with whom they were already involved. Fears about jeopardizing their working relationship and not knowing how best to proceed had meant that, while much energy had been put into planning and advertising the group, the health visitors had not mentioned it to any of their clients. The question that the consultation needed to focus on was refined as: What skills can I use to raise the issue of smoking with my clients?

(iii) Developing the methodology

After this initial consultation the consultees and consultants agreed to meet for four further consultation sessions, which would focus on frameworks and skills for working with smokers. The health psychologist and health promotion officer planned these sessions to include using the Stages of Change model (Prochaska & DiClemente, 1982) in order to provide a framework with which to structure health promotion interventions, explore and practise some communication skills (e.g., open and closed questions), and choose and use health promotion materials appropriately.

(iv) Implementing the methods

The four sessions went ahead as planned. The health visitors were asked to do work between each session. This included using a case study from their own work to apply the framework presented, and reviewing a health promotion resource for its usefulness and appropriateness for their client group. The feedback from the health visitors on the sessions was very positive, and the sessions were slightly refocused to concentrate on basic communication skills and assessing clients' health beliefs.

(v) Reporting back

The final session was used to review what had been covered and discuss the training and development needs identified. Preliminary evaluation of this consultation indicated that this was a useful and valued way of working. In particular, consultees identified the benefits of being able to focus on skills in a small-group setting and of sharing their experiences of smoking cessation work in a structured way. The importance of offering this approach in a systematic way to other groups of health visitors was identified.

8.06.6.3.3 A consultancy framework for developing health promotion intervention programs

The examples given above demonstrate the similarities in requests for consultation. The three main issues focused on in health psychology consultancy were:

(i) offering support for, and an opportunity to review, skills development;

(ii) using health psychology models to provide frameworks to help consultees review their approaches to, and planning of, health promotion work; and

(iii) developing intervention programs.

It was decided to use this framework to develop a consultancy service that would allow the health promotion unit to develop health promotion programs in conjunction with primary care teams. An example of this work that led to the development of a weight management program is described below.

(i) The Approach from the consultee

The health promotion officer for exercise and nutrition was approached by two practice nurses who wanted to set up a group program in their practice for patients with weight problems. This officer was interested to work with the CHD health promotion officer to develop a program. The health promotion officer asked the health psychologist for support and help with this work and for advice on including a psychological perspective.

(ii) Refining the question

Initial meetings were held with the two health promotion officers to agree on the focus of the work. Their aim was to develop a joint working relationship with the practice nurses to allow for skill sharing in the development of a group program. The health promotion officers could offer health promotion skills, knowledge of the topic and its health implications, and knowledge of health promotion materials for running group interventions. The practice nurses had experience of working with this client group and facilitating groups. After discussions it was agreed that consultancy sessions would be used to review the development of this working relationship. The question was refined to become: How can we establish a working framework with primary care to develop an intervention program? A number of features of this relationship were identified that were to be reviewed in each consultancy session: the timing and setting of meetings between both groups; the issues raised, including any difficulties and how, or if, they were resolved; opportunities to discuss skills and approaches and to share concerns with regard to the group itself; and the use of health promotion materials. The final issue that was considered in consultancy sessions was how to capture the learning from this method of joint working.

(iii) Developing and implementing the methodology

A series of joint sessions with the health promotion officers was planned in which the above topics would be reviewed. These sessions took place on a weekly basis subsequent to the health promotion officers' meetings with the practice nurses. The sessions included feedback from the health promotion officers on the progress of the group. The health psychologist facilitated a review, using an acceptant consultancy style, of the issues that were raised, and the above points were considered each time.

(iv) Reporting back

The health psychologist kept a record of the consultancy sessions, and the final sessions were used to summarize the issues that had been raised, in order to identify further training and development needs and to consider how to capture the learning from this process. It was decided to write up the work in a way that would capture both the content and the process of learning for both the practice nurses and the health promotion officers. This led to the development of a weight management program pack, which was later piloted in another practice.

8.06.7 THE FUTURE: AVOIDING GAPS AND TRAPS

One general problem of consultancy is that health professionals may feel threatened by asking for psychological consultation (Belar, 1991). The request for help may reflect a breakdown in communication or relations between people, and may be a challenge to self-esteem, especially in health care settings where people are expected to have expertise in these areas. Empathy for the perspective of the individuals and the staff groups involved and tact to handle these situations are essential. Whilst these subjective factors may put limits on the consultancy role, the objective potential for the future is favorable.

In considering the future role of psychology in health care settings, Siegel (1995) wrote:

> An emphasis on cost containment, quality assurance, accountability, and documentation of health care programs' effectiveness will necessitate the use of psychologists' research and program evaluation skills. These developments will provide psychologists with the opportunity to have a significant role in shaping health-related programs for prevention and in the delivery of services. (p. 342)

and, as was confidently stated in 1987,

> there are few limits to the issues a health psychologist with vision, dedication, and persistence can address [but] the responsibility for forging new pathways lies on the shoulders of the entire health psychology community. (Altman & Cahn, 1987, pp. 240–241)

However, as psychologists know only too well, there is often a large gap between intention and behavior. We need to use the strategies identified by psychologists to bridge this gap, in the development of our own future, and we need to avoid the trap of the individualism that has sometimes been associated with psychologists. Instead, we should plan, organize, and act as a collective.

ACKNOWLEDGMENTS

Susan Michie is supported by the Wellcome Trust. The author thanks Louise Earll and Barbara Wren for comments on an earlier draft of this, and Barbara Wren for contributing the section on her consultancy work in primary care.

8.07.1 INTRODUCTION

In addition to the assessment, treatment, and prevention of health problems as described in other chapters of this volume, health psychologists have a valuable role to play in teaching and training members of other health-related disciplines. This chapter will outline the possibilities, some of which, such as communication skills teaching, are being applied widely in health education internationally, while others such as encouraging surveillance of the occupational health of health workers, remain underdeveloped.

This chapter begins by introducing the key health professions other than psychology, and briefly reviewing the psychological content of their curricula (Section 8.07.2). Section 8.07.3 then describes the desirable outcomes of health psychology within training for health professionals, in terms of three broad goals: improving the health of the community, improving the health and well-being of health workers, and imparting relevant knowledge and skills to health workers.

The chapter then reviews the format and methods which seem to be most effective in such teaching (Section 8.07.4). Traditional lecture and tutorial methods need extension for professional training, and health psychology teaching is characterized by multidisciplinary collaborations. Section 8.07.5 lists the health psychology topics likely to be widely useful to health professionals, and therefore recommended for inclusion in their educational preparation. Finally, Section 8.07.6 raises some wider issues about what qualities are needed in the health psychologists who do such teaching, what their own needs are, and what the consequences of sharing our knowledge may be for health psychology.

8.07.2 KEY HEALTH PROFESSIONS

This chapter will concentrate on the health disciplines which receive preregistration training in universities, including institutions of higher education which were formerly known as colleges of advanced education, polytechnics, or institutes of technology. Other disciplines which promise health care but for which training generally occurs outside universities include chiropractice, naturopathy, hypnotherapy, aromatherapy, and so on. While these "alternative" treatments sometimes win acceptance from doctors and nurses who recommend them to their patients, little information is publicly available about their training curricula or assessment methods. However, at least some of the material in this chapter seems likely to be applicable to them too.

Many health professions provide continuing education for their members after entry to the workforce, in the form of workshops, seminars, conferences, and journals, either on a voluntary basis or in a formal way overseen by registration or professional bodies. With recognition of the ever-faster expansion of knowledge, and acknowledgement that undergraduate instruction cannot suffice for a life-long practicing career, we may expect that some form of regulated continuing professional education will become more rather than less common. Thus postregistration health psychology teaching and training seems likely to increase in extent in the relatively near future. Everything said below about mutual collaboration between health psychologists and members of the profession concerned, applies with even greater force to postregistration teaching.

A great deal of variability exists in the methods and content of teaching health psychology to different sets of students. When we multiply the variations within different professions, undergraduate vs. postgraduate courses, teaching institutions, cities and countries, it is clearly unrealistic for a chapter such as this to give a detailed account of hours spent, methods used and course content in every case. Rather the goal here will be to convey a flavor of what aspect of health psychology are taught in the nonpsychology disciplines, largely based on a review of published textbooks. Learning via the Internet, which has been predicted to change academic methods radically, will be discussed later (see Section 8.07.4.1.4).

Published teaching materials are probably only a small proportion of those in use. The existence of a textbook indicates that somebody, perhaps an individual, probably a curriculum committee but certainly a publisher, perceived a need for that educational resource. However every teacher is well aware that published materials may not accurately represent the examinable content of the course, and even less do they reflect the methods used to teach it. Another major problem for the comprehensiveness of a review such as this is the fact that we have limited understanding of the relationship between the teaching provided, and what students learn. Doubtless the teachers' credibility, skills, knowledge, enthusiasm, and similar factors mediate how the teaching is received and therefore what impact it may have on the later professional practice of graduates. Apart from some comments on when and by whom teaching should occur (in Section 8.07.4), such issues are beyond the scope of this chapter, but do need systematic attention and research by educators.

The main health professions described below are not in order of status within the health care industry, nor in order of the competition for places and thus the prior academic qualifications of the students. Current numbers of Australian students have been chosen as an ordering principle. The health education system in Australia is very similar to the British, and Australian health professionals are found all over the world. While the number of students may not be proportional to the number of practitioners, it is reasonable to use student numbers in a chapter on training because the great bulk of formal training occurs before professional registration and practice.

Table 1 shows the numbers of health and social work students who were enrolled in higher education in Australia in 1995. An average of 6.5% of students across health disciplines came from overseas and were paying full fees, with the highest proportions being in pharmacy (14%), medicine (12%), and dentistry (11%). Overseas students mostly speak English as a second language, and language-rich subjects such as psychology need to provide extra support and language tuition to help them succeed. The most effective support includes discussion of cultural assumptions as well as language help (Ballard & Clanchy, 1991; Chur-Hansen & Barrett, 1996). Asian and European cultures have different norms and expectations about health-relevant behavior, challenging what has sometimes been an unself-conscious Anglocentrism in health psychology. In health and health care, cultural differences in beliefs and practices need to be understood by teachers and trainers as well as by practitioners. To a less marked extent the same point applies to students of different social class backgrounds within the same language group.

8.07.2.1 Nursing

In terms of student and practitioner numbers, the discipline of nursing is the dominant healthcare profession: there were three times as many nursing students as medical students (see Table 1).

Nursing education has established itself in Australian universities since the early 1980s in contrast with the previous apprentice-style, bedside teaching methods (McCue & White, 1983). A recent review of nurse education concluded:

> The need now is to move beyond the era of the transfer [of nursing to higher education] . . . [to] the development of professional practice, the growth of nursing as an academic discipline, and the future contribution of education and research to the quality of nursing care. (Reid, 1994, p. 341)

This review identified as core curriculum:

> basic strands in the areas of medical/surgical nursing, community health nursing, and mental health nursing, for individuals across the lifespan in institutional and noninstitutional settings [including] communication, primary health, behavioral sciences, biological sciences and broadbased, general health care subjects. (Reid, 1994, pp. 170–172)

Doctor–nurse relationships have been described by sociologists and anthropologists (e.g., Campbell-Heider & Pollock, 1987) but there is now an interest among nurses themselves in understanding the political dimensions of health care and in improving community health through active advocacy (Gray & Pratt, 1992). The establishment of doctoral training programs in nursing which include coursework and fieldwork in addition to research training is intended to assist nurses who seek careers in consultancy, management, and policy making (Pearson, 1996). In the USA there is a very wide choice of masters and doctoral programs for nurses.

At the undergraduate level there is longstanding and continuing interest in the psychological aspects of nursing (Byrne & Byrne, 1992; Hall, 1982; McGhie, 1973, Paton & Brown, 1991; Payne & Walker, 1996). One of the few texts to identify itself specifically as health psychology for nurses (Niven, 1994) includes in its preface an explicit articulation of a crucial issue in health psychology training for all nonpsychologists—namely what is the most desirable framework to adopt? Whereas early texts in nursing as in other health disciplines tended to adopt the framework of what aspects of psychology might be relevant to health care, Niven adopted instead the framework of a psychology of health. Taking health rather than psychology as the primary focus need not in fact result in vastly different contents from those of the more traditional approach (although they will be differently arranged and presented), but seems likely to have the important pedagogic advantage of being more attractive and credible to students (see Section 8.07.4).

8.07.2.2 Medicine

Medical courses have included psychological content, often under titles such as "behavioral science," "medical psychology," and "behavioral medicine," for many years now (DiMatteo, Friedman, & Robin 1982; Hetherington, Miller, & Neville, 1964; Pomerleau & Brady, 1979; Rachman, 1977; Stoudemire, 1994; Wedding, 1995; Weinman, 1987; Winefield & Peay, 1991). Health psychologists have seized the opportunity to teach medical students and thereby develop relationships with medical practitioners and engage in collaborative research (Winefield, 1991). While the technological advances of the post-World War II period have fostered a strong emphasis and high prestige within medicine for pharmaceutical, surgical, and diagnostic techniques—in general the "bio" element within the "biopsychosocial" model of health care (Engel, 1977)—health psychology with its focus on behaviors, beliefs, and feelings in relation to health and illness, adds the balance of a multivariate and holistic perspective on health care and health promotion.

Just as clinical psychology has experienced border disputes with the medical specialty psychiatry, health psychology seems most likely to compete with consultation–liaison psychiatry, the clinical derivative of psychosomatic medicine with its interests in cardiovascular disease, oncology, and chronic pain (Wise, 1986). Some clinical health psychologists spend their time in the delivery of services to individual patients, but others such as occupational health psychologists work in ways more congruent with public health (Quick, 1996).

8.07.2.3 Medical Social Work

The 1991 Australian census indicated that 35% of social workers will work in health settings (Martin, 1996), thus justifying the inclusion of this profession here. This profession shows large national differences in its organization; in the USA, for example, social workers much more often practice autonomously than in Britain and Australia.

Teaching materials tend to have a strong practice orientation (Danbury, 1994; James & Vinson, 1989; Shulman, 1993), although Thompson (1995) has argued in favor of integrated theory and practice. Developmental and social psychology seem to have been most valued, but social workers in medical settings may learn to welcome health psychology input.

8.07.2.4 Physiotherapy/Physical Therapy

This discipline, like others traditionally seen as "adjunct," "allied," or even "para" in relation to medical services, was once taught using an apprenticeship model within the work (usually hospital) setting. Physiotherapists use exercise, manipulation, and physical interventions such as heat and ultrasound to treat problems of pain, restricted movement, and the consequences of injury or aging. An early textbook by Dunkin (1981) focused on learning, individual differences, and interpersonal relations, and encouraged students to search the literature to follow up their interests.

8.07.2.5 Occupational Therapy

The practice of this discipline seeks to foster the health benefits of occupation, in the sense of purposeful activity, especially for persons with psychiatric, intellectual or physical disabilities. While virtually theory free in the past, the profession recognizes a need to identify and evaluate its skills and to prepare practitioners for work in a variety of settings (Fransella, 1982; Kielhofner, 1992).

8.07.2.6 Pharmacy

The Report of the Study Commission on Pharmacy (1975) found an imbalance in the curriculum of the day, with too much attention being given to drug products and their effects and too little to "human behavior, cultural determinants, health service systems and their economics. ... Needed and optimally effective drug therapy results only when both drugs and those who consume them are fully understood" (pp. 126–127). Wertheimer and Smith (1989) aimed to redress this imbalance, including readings on topics such as the patient's view of the illness, compliance, choices of prescribed and nonprescribed drugs, tranquillizers and social control, and ethics and informed consent. Public attitudes to medicines, which seem to be increasingly ambivalent (Vuckovic & Nichter, 1997), need to be understood by many health professionals in addition to pharmacists.

8.07.2.7 Dentistry

Textbooks on the psychological aspects of dental practice have been available for some time (e.g., Ayer & Hirschman, 1972; Cinotti, Grieder, & Springob, 1972). Obvious topics of interest include dental anxieties and phobias, bruxism, oro-facial pain and compliance with self-care or orthodontic instructions.

8.07.2.8 Speech Pathology/Therapy

Disorders of oral communication whether due to childhood lack of skill development or to loss of skills after stroke or head injury occupy speech pathologists, who treat them using graded exercises. Purser (1982) was an early contributor to their understanding of developmental and social psychology and behavior change.

8.07.2.9 Other Health-related Occupations

Various forms of medical scientist, and support professions such as radiography, dietetics, podiatry (chiropody), and health administration are also taught in universities. It appears that their curricula are task-focused and in some cases their direct service roles limited; where health psychological input is required it may well be taught using materials originally prepared for other disciplines, or specific to the course and not commercially available.

8.07.3 MAJOR GOALS OF HEALTH PSYCHOLOGY TEACHING

The health psychology input for health profession students does not need to be uniform in format or content across courses. Indeed health psychology courses need to be geared sensitively to the practice modes, traditions, and expectations of practitioners of each discipline. For example other professions vary in whether they see their discipline as a science or a craft, how independently they expect to practice, and where practice usually occurs, as well as in the academic achievement levels and backgrounds of incoming students. In this section of the chapter, however we will canvass some broad goals which could apply to all health psychology input. Section 8.07.6 will address the controversial issue of what the consequences for health psychology might be, of "giving psychology away" to other disciplines.

8.07.3.1 Improved Healthcare

Most teachers, trainers, and curriculum committees would probably agree that the main purpose of including health psychology is to improve the quality of healthcare which students are later able to deliver. In Section 8.07.3.3, I shall try to distinguish some superordinate skills of the well-taught and well-trained health professional, to which health psychology has contributed.

A secondary goal of course organizers might be for health psychology itself to gain recognition and respect amongst other health professions, and for health psychologists to develop useful professional networks and access to research opportunities by being visible and successful within the training institutions.

A large practical and conceptual obstacle to devising a successful health psychology course, in terms of knowing that it is contributing to improved healthcare, has been the lack of markers or indicators for quality of health care practice. When no data are available about how successful various practice interventions are, either in improving patients' quality of life or in reducing their symptoms and death rate, the role of health psychology knowledge and skills (as with every other component of the students' learning experiences) becomes difficult to judge. Presently there is increasing awareness of the need for health professions to develop appropriate outcome measures, to validate them, and to begin the process of exploring their antecedents (Kaplan, 1994a).

8.07.3.1.1 Measurement of quality of care

Life expectancy has improved in developed countries following the great public health reforms of clean water, sanitation, public education about hygiene, nutrition, and prevention; and accessibility of antenatal care, child health screening, and emergency services. However, mortality rates are insufficiently sensitive as outcome measures of many health care interventions, particularly given the chronic nature of much illness in developed countries. Ongoing measures of health are needed which will reflect changes over time in both physical and psychological dimensions. Health-related quality of life (QOL), a concept which embraces affective and social well-being, functional capacities, and lack of symptoms, is an outcome measure well-suited to the evaluation of the effectiveness and cost-effectiveness of health care (Kaplan, 1994a, 1994b; Ware, 1995). An example of the latter analysis is that some preventive and educational interventions have much greater payoff in terms of "cost per well year," than more specialized surgical treatments. Specifically, costs per well year in 1991 US dollars of seat belt laws = 0, of smoking cessation counseling = 6463, and of coronary artery bypass graft for heart disease = 662 835 (Kaplan, 1994a). The development and standardization of QOL measures is widely agreed to be a top priority project for health psychology (Sarafino, 1994; Weinman, 1990).

Patients are often forced to rely at least in the short term, on interpersonal features of the care-delivery interaction to assess its value. Some of these "process" features have been shown to correlate with beneficial health outcomes although the relationship is not straightforward (Kaplan, Greenfield, & Ware, 1989; Stewart, 1995).

"The patient is now ... to some degree an adjudicator of service quality ... [which] means that the doctor's perspective on what is valuable in this interaction ... is marginalized" (Fairhurst & May, 1995, pp. 389–390). Patient satisfaction with care is a proximal measure of quality of care but cannot be accepted as adequate by itself. Apart from the likely response-biases when seeking feedback from people who may need help again soon, there are problems in accepting patients' definitions of what they need. Some patients may have unrealistic expectations of what can be achieved, or of how much time the health worker can devote to their case. Others may feel most secure only after numbers of extra diagnostic tests, investigations, and treatments which are regarded as unnecessary and excessive by their health carers, and/or by the insurers and administrators who oversee health care costs (Aharony & Strasser, 1993; Pickering, 1993; Williams, 1994). Another difficulty is that patients' satisfaction with an episode of healthcare may change over time, and not be validly captured by a questionnaire after a single consultation (Avis, Bond, & Arthur, 1997).

Nonetheless, there are compelling arguments for seeking evaluative information from users of health care services. In industrialized countries the individual consultation between a patient and a general practitioner, for example, only rarely results in dramatic improvements in the health of the person concerned (Winefield, Murrell, & Clifford, 1995). Often, patient satisfaction with the experience of being cared for may be the only measurable outcome of a health care interaction, but this sense of being cared for and valued by credible experts can have powerful nonspecific benefits (Shepherd & Sartorius, 1989). An example is the finding by Fitzpatrick, Hopkins, and Harvard-Watts (1983) that headache sufferers were more likely to report fewer and less severe headaches one year after referral to a neurology clinic, regardless of what, if any, medication was prescribed, if they had felt satisfied immediately after the consultation. The popularity of alternative healthcare practitioners with the public has been attributed to their willingness to spend time, show interest, and develop a caring personal relationship with the "client"; these factors plus the shared rationale for illness and the confident prescription of healing activities are also common to nonmedical healers in other cultures (Frank, 1989).

8.07.3.2 Health and Well-being of the Health Workers

A secondary goal of including health psychology in courses for other professions might be seen as preparing them not only to deliver health care to patients/clients, but to maintain their own health and well-being while doing so. The high turnover in some health professions, particulary nursing where there are many back injuries, and the reports of high job stress, career dissatisfaction, burnout, and associated problems of alcoholism, drug abuse, and marital strains (Allen, 1994; Howell & Schroeder, 1984), provoke consideration of the need for some preventive educational preparation.

Students often enter health courses when quite young (many are teenagers direct from secondary school, in Australia and Britain), and with relatively little life experience. The higher the academic qualifications for entry, it seems the less opportunity students have had to mix with people outside their own peer group, people of different ages, social class and cultural background, and to explore their own talents and interests beyond study. It is not surprising therefore that the demands of tertiary study—often combined with financial pressures and personal development issues around independence, sexuality, and vocation—in combination with the exposure to illness, suffering, and death, can be stressful for students (Ashton & Kamali, 1995; Firth-Cozens, 1987; Simpson & Budd, 1996).

The role models available to students in clinical settings may or may not be positive examples of healthy coping. There is a delicate balance between maintaining a degree of professional detachment which facilitates action but still expresses care and respect for the patient, and an emotional distance which patients and professionals alike find unsatisfying and depersonalizing. Getting this balance right is possibly the hardest task in professional training, or certainly the most psychologically challenging aspect, and clinical health psychologists may have valuable roles as both teachers and therapists.

After graduation, other work-related pressures are added. Autonomy, a traditional reason for job satisfaction in medicine for example, is perceived as being eroded through the intrusion of third parties such as insurers, administrators, and managers (Allen, 1994; Burke, 1996; Siegler, 1993). An awareness of the psychological hazards of healthcare is the first requirement for prevention, so that affected individuals do not castigate themselves as weak and inadequate. This awareness can be raised during undergraduate years and may subsequently need reinforcement with stress management interventions (Bunce & West, 1996; Midence, Gregory, & Stanley, 1996; Quick Murphy, & Hurrell, 1992).

8.07.3.3 Knowledge and Skills from Health Psychology Input

In this section I shall review some general categories of health psychology knowledge and skills which, in the context of the restrictions described above on how to recognize quality care, could be expected to equip students for their future work in health professions.

First it is relevant to draw the distinction between "knowledge" which is acquired through teaching, and "skills" which are acquired through training. While the distinction cannot be rigidly applied, it usefully indicates different types of learning and the activities meant to promote them. Traditionally, health students have acquired knowledge in an abstract way through lectures and readings, assessed through exams, then proceeded to acquire clinical skills though supervised "hands on" practice, assessed to competency standards by experienced practitioners. The knowledge acts as a foundation for the skills but also goes further to give students a general appreciation of the theoretical and conceptual roots of their discipline and its methods of accumulating further knowledge. It is also meant to equip students to read critically, to continue their education life-long, and possibly to contribute to the knowledge base of the discipline themselves by engaging in research.

Skills have the more immediate practical value of equipping students to deal effectively with their work tasks. As well as being capable of giving injections, bandaging, and a host of other physical procedures, health professionals have to develop cognitive skills of clinical decision-making and time management. They must learn to respond calmly and automatically in distressing or life-threatening situations and to cope with behaviors, injuries, or disfigurements which untrained members of the public would find overwhelming. Skills can also become obsolete, and re-training or revision of them is then needed.

While each health profession has a more or less specific knowledge base and distinctive skills, health psychology can contribute important general elements which are identified below. Each of them could usefully become a strand of instruction, taking different forms with progression through the course (see Section 8.07.4), but with continuity throughout it. More specific topics are listed in Section 8.07.5.

8.07.3.3.1 Communication skills

Every health practitioner needs to develop effective communication skills. These include being able to access information from the patient which is relevant to diagnosis and treatment, to explain matters using comprehensible terms (including written materials) and to check patient understanding, to encourage patient questions, to listen attentively, to communicate respect and care, and to persuade service-recipients to follow recommended patterns of self-care after the consultation ends (whether taking medications, changing health habits, making a follow-up appointment, etc.). These skills were identified largely through research into the outcomes of psychotherapy (Greenberg & Pinsof, 1986; Stiles, Shapiro, & Elliott, 1986; Strong & Claiborn, 1982) and acquiring them is a clear case of behavioral training via graded steps. A great deal is now known about teaching such skills (Cushing, 1996; Byrne & Byrne, 1996; Dickson, 1989; Egan, 1994; Evans, Stanley, Mestrovic, & Rose, 1991; Froelich, Bishop, & Dworkin, 1976; Kimberlin, 1989; Winefield, 1992).

To be most effective, the communication process will often need to take into account how patients' responses and needs are affected by their psychosocial development, age, education, level of anxiety and cultural background. Thus flexible communication skills need sound psychological foundations.

Skilled communication increases patient satisfaction and compliance, reduces the rates of malpractice litigation, and achieves nonspecific (placebo) benefits, all of which may additionally contribute to the health worker's job satisfaction. Public health benefits can follow from targeted communications or information campaigns with health-promoting or educational messages. These require rather different sets of skills from the one-to-one interactions which are the present focus.

Health workers also need skills in communicating with their colleagues, superiors (clinicians, managers, and administrators), members of related disciplines, and often with the relatives or friends of the designated patient. Less commonly but just as critically, health professionals may need to communicate effectively with politicians, accountants, and other decision-makers. So far none of these skills has received as much attention as the skills for communicating with patients, yet they may prove vital in securing community support and resources for effective health care to proceed.

8.07.3.3.2 Understanding of and respect for scientific enquiry

It does not need a high-flying mathematical background (though some health students have that) to comprehend the basic concepts of experimental design such as matched control groups, random allocation to treatment or control groups, standardized outcome measures, and credible lengths of follow-up. Also practitioners of every discipline need to be aware of the nonspecific or placebo influences on healing which are independent of discipline-specific treatment techniques, whether pharmacotherapy, spinal manipulation, or craft activities. The psychological and therefore physical benefits of trust, hope, a sense of control and a sense of self-worth are relevant both to "feeling better" after contact with health professionals and also to the whole range of self-care (compliance) and preventive activities by the patient.

If students do not learn about the need for untreated and placebo control groups and about how to evaluate claims of treatment efficacy, there is a risk of inflated beliefs about the impact of their own discipline's specific effectiveness (an example perhaps being claims for the rehabilitation of torture victims by physiotherapy (Bloch & Moller, 1990). Evidence-based healthcare, which means using the best techniques available according to pooled high-quality information, will increasingly be demanded by health-management organizations as well as by health professionals concerned to offer the best care (Friedman, Sobel, Myers, Caudill, & Benson, 1995; Sackett, Rosenberg, Gray, Haynes, & Richardson, 1996). The access to information offered by the electronic revolution in information technology will help, but the attitude of curiosity and willingness to learn remain vital. Confidence in one's own capacity to evaluate claims and remain an active self-educator, as well as to work with collaborators from a variety of disciplinary backgrounds, depends on this basic ability to assess the evidence—an ability which is not specific to health psychology but which psychologists have great experience and expertise in imparting (MacLeod & McCullough, 1994).

The psychologist's skills in research design and methodology, standardized measurement, and statistical analysis are increasingly valued by other health disciplines, as the sophistication of their research rises. Even where health students cannot become expert in these matters themselves, they can acquire a respect for the scientific approach to understanding human behavior, and the cognitive tools to ask critical questions of their own research literature and other sources of claims about new treatments. There is a permanent gain from having learned how to appraise the flood of information to which students are likely to be exposed during their working lives, and to develop tools for assessing its value and meaning.

Once data have been collected and analyzed, and even after a scientific paper has appeared in a prestigious journal, much remains to be done to translate the findings to improve community health and to ensure the sustainability of interventions after the researchers leave (Altman, 1995). Action research principles (Greene, 1988; Hart & Bond, 1995; Whyte, 1991) take seriously the obligation of researchers to ensure visibility of their work to decision-makers. Often this involves collaborating actively with key stakeholders from the community in order to gain access to subjects and measurements, as well as help in publicizing the results and ensuring their conversion to policy (Altman, 1995).

Another development within health psychology research which owes some impetus to health professions other than psychology, is the relatively recent interest in qualitative research methods (Patton, 1990; Waitzkin, 1990). Triangulation, the combination of quantitative and qualitative approaches in the same investigation can be extremely fruitful, as shown for example in recent studies of occupational stress and health in a factory by Baker, Israel, and Schurman (1996), and of the complex determinants and consequences of patient participation in consultations by O'Brien and Petrie (1996).

8.07.3.3.3 Appropriate patterns of practice

The ability to monitor one's own professional performance increases recognition of the limits of one's own disciplinary expertise, while failure to know one's limits is probably responsible for some of the worst cases of mismanaged health care efforts.

With the typically crowded curriculum of health disciplines, the health psychologist teacher will be able to give practical training in communication skills but not in performing psychological diagnosis or managing behavior change. Gaining an understanding of the principles of the latter two areas will allow nonpsychologist professionals to make effective referrals to specialist services including from clinical health psychologists (Belar, Deardorff & Kelly, 1987; Winefield, 1996).

The psychological awareness and the rejection of a narrow biomedical perspective which are the desirable outcomes of health psychology teaching, can be usefully applied by other professions not only to their interactions with patients but also to reflections on their own work practices. Health professionals need a sensitivity to the causes and effects of job stress in themselves and their colleagues, as the unproductiveness and danger inherent in dissatisfied, stressed, and impaired professionals is considerable (Jones et al., 1988; Keltner & Leung, 1995; Nuffield Provincial Hospitals Trust, 1996). All health workers should receive some educational preparation about the psychological as well as physical hazards to their safety and well-being, be capable of detecting signs of emotional exhaustion and other signs of strain in themselves and colleagues, and know how to proceed next.

Occupational health psychologists may be valuable to develop job stress management interventions for health workers and more broadly, to help health professions to select, train and monitor their members to prevent occupational stress and its damaging consequences for both practitioners and patients (Landy, Quick, & Kasl, 1994). Governments may not welcome such initiatives if they lead to calls for shorter working hours (e.g., for junior, salaried doctors in training), better working conditions (e.g., not being forcibly sent to rural locations), more support from psychologists, and policies to reduce environmental and social causes of illness such as air and water pollution, unsafe workplaces, poverty, racism, unemployment, and unequal access to education and health care.

8.07.4 FORMAT AND METHODS OF TEACHING

The following comments, about how health psychology should be included in courses for other professionals, need to be seen within the context described above of (i) different practice traditions and expectations in each profession, and (ii) difficulties in comparing the effectiveness of different teaching methods due to lack of definition of the desired outcome: high-quality health care.

Beginning teachers may find they have little autonomy to decide course content or teaching methods, and that crowded student timetables allow little flexibility. The health psychologist will then need to gain the trust of other faculty members as in any relationship between a service provider and a client.

There are no agreed formulae for ensuring student interest in and usage of health psychology material, as with other parts of their curriculum. In fact some students who enter their training with unrealistic ideas of the biological nature of health care, or who have limited tolerance for ambiguity, may be expected to find health psychology quite aversive. On the other hand some may find this holistic perspective a very welcome change from more molecular approaches. Evaluative feedback from students through anonymous ratings has many of the same problems as a measure of teaching quality as does patient satisfaction as a measure of health care quality. However, the very fact of staff showing concern about the students' response can raise their morale.

8.07.4.1 Lectures or Practice?

Swerissen and Foreman (1991) advocate utilizing different teaching methods for the "knowledge" and the skills or "application" strands of health professional courses. One strand uses lectures to teach health-focused psychological knowledge including psychological factors in illness and recovery, behavioral risk factors, stress and pain, and reactions to illness, hospitalization, disability, and death. The other strand consists of training vocationally-relevant skills such as communication, research and program evaluation, case management, and compliance strategies, and is taught to competency standards with supervised practice in applied settings. This was the procedure explicitly accepted by Niven (1994).

The second strand especially, is time- and labor-intensive and demands a cadre of trained health psychologists to act as tutors and supervisors. Yet this is likely to be the component of the course which ensures student respect for and retention of the more theoretical knowledge.

8.07.4.1.1 Lectures

Although listeners retain only a fraction of a lecture's content afterwards, the efficiency of one person presenting carefully selected material to a large class ensures the survival of this teaching technique in most establishments. On the whole, anything which increases the active participation of students, such as questions, short sessions of discussion ("buzz groups"), or segments of audiovisual material, is likely to improve student attentiveness (Newble & Cannon, 1994). Guest lecturers who use clinical examples to illuminate the connections between their daily work and the course material, can also stimulate student interest.

8.07.4.1.2 Structured observations of practice

Clinical settings can bewilder novice students, who often feel confused, superfluous, and embarrassed by their own lack of knowledge. Observing what a hospital is like, and how difficult it is to get information into and out of the system, can be valuable, but specific efforts to link observations to course material (for example, to report back on communication interchanges or behavior influence attempts) oblige students to process what they observe in the terms of psychological concepts. Debriefing may sometimes be required after the observation of negative models: entry-level students in particular have a capacity to identify with the patient and this furnishes powerful teaching opportunities.

8.07.4.1.3 Small (tutorial) group learning

A group of up to a dozen or so students which meets regularly with a tutor who adopts an egalitarian role and who facilitates active problem-solving, can provide both social and educational benefits. Again, adding structure to the meetings rather than always relying on spontaneous discussion, can increase motivation by making participation in group meetings assessable. Assignments to be carried out between meetings can include small fieldwork projects (ask new parents about early attachment experiences, find examples of different types of human conditioning, monitor own heart rate and emotional state, etc.) or involve critically reviewing a pertinent journal article. Demonstrations of diagnostic methods (including psychological ones), experiences of muscle relaxation training, and whole sessions devoted to independent group research on a topic for subsequent presentation are other useful activities.

In early stages of skill acquisition, group demonstrations and rehearsals in a nonthreatening environment are a good way to begin. One very natural application of this is in communication skills training, where feedback from standardized patients and group support can help to overcome self-consciousness. Assessable practice tasks and cumulative learning across course-years ("vertical integration") then build skills to the point of clinical competence.

The peer supportiveness which can emerge from a group such as this, and the experience of cooperative mutually helpful work, can be valuable learning experiences in themselves (Lucero, Jackson, & Galey, 1985; Newble & Cannon, 1994). Although work in the health professions is often collaborative and interdisciplinary, too often competition rather than cooperation is the norm between students, and skills in building constructive team dynamics are frequently neglected (Rowe, 1996).

8.07.4.1.4 Learning via the Internet

Computer Aided Learning (CAL) modules have been available for health students for some time, but the focus was initially on biological rather than psychosocial content. However, a consortium of British universities is now working to produce a set of CAL programs on behavioral science topics including pain, child development, clinical decision-making, changing health beliefs, managing stress, and quality of life measures.

The Internet, an exponentially expanding source of information, opinion, and marketing efforts, promises to revolutionize access to knowledge for both students and teachers. Methods not only of instruction but of assessment will consequently be modified. It will be all the more important for students to learn how to evaluate claims and develop critical thinking skills, in order for them to exploit this medium effectively and with discernment.

8.07.4.2 Integrated, Problem-based Learning

Just as education in nursing, physiotherapy, and some other disciplines is moving from the hospital to the classroom and increasing its scope and formality, medical education which has always been carried out in universities is in a sense moving in the reverse direction, with increased emphasis on "problem-based learning" (PBL) which blurs the old preclinical–clinical boundaries (Engel, 1992; Kaufman, 1985). In this approach a small group of students is presented by videotape, audiotape, or in writing with a carefully-constructed clinical case, and over the course of a series of meetings with their tutor, decide what information they need to solve the problems presented. Learning is thus thematically organized rather than discipline based, and is cumulative and learner directed. The goal is the development and enhancement of active reasoning and problem-solving skills rather than passive and superficial rote learning.

Norman and Schmidt (1992), although finding no evidence that PBL improves content-free problem-solving, reported that it enhances transfer of concepts to new problems and of basic science to clinical problems, and that it enhances intrinsic interest and self-directed learning skills; a gain which is maintained. Dolmans, Gijselaers, Schmidt, and van der Meer (1993) investigated whether students miss out on crucial curriculum material when staff are not in control of what they learn, which is one frequent concern with PBL for students and teaching staff. They reported a 64% overlap between faculty objectives and the learning issues generated by students, and that students also generated relevant learning issues not expected by the faculty. Low overlap of student- and staff-determined content could be used to screen out or reformulate unsuitable problems.

Part of the difficulty in evaluating the effect of a PBL curriculum in comparison to a more traditional format lies in the fact that students who are drawn to PBL may be different from the others. For example Cariaga-Lo, Richards, Hollingsworth, and Camp (1996) found that PBL entrants had higher admission test scores and were more self-reliant. Where the whole curriculum has become problem-based, Kaufman and Holmes (1996) found a favorable response to the change in students, tutors, and faculty staff, and identified four strategies which they believed had facilitated this acceptance, namely in-service training, resource support, feedback mechanisms, and participation in decision-making.

8.07.4.3 Assessment

To be congruent with the goals of PBL, reasoned decision-making rather than recall should be built into the assessment procedure (Engel, 1992). Taking this to its logical conclusion implies some reliance on self-assessment of progress towards self-selected goals (Kaufman, 1985; Lofgren & Lundahl, 1996; Ryan, Little, Smith, McMillan, & Hengstberger-Sims, 1992). However in practice a place for external assessments is likely to be maintained, due to the demands for credentials, public accountability and rank-ordered access to the most desirable training posts.

Written examinations in health psychology lend themselves to essay-type answers rather than to multiple choice questions. Although the marking is relatively more labor intensive, the teacher has the satisfaction of knowing that students are practicing a valuable and relevant skill (written communication), and that such methods are supposed to foster deep as opposed to superficial learning. Assignments in fieldwork or independent research can also be presented for assessment in written form, thus reducing the proportion of the assessment which is derived from examination papers, and providing students with a souvenir of the course which they may find instructive to retain. A real acceptance of responsibility for their own learning by students, will hopefully reduce the temptations of plagiarism which becomes more and more difficult for teachers to detect.

The assessment of practical skills needs other approaches. Segments of audio- or videotape can illustrate the student's level of competence in the early stages, for example, of communication skills acquisition, to be followed later by observed performance in standardized situations such as an objective structured clinical examination (Hodges, Turnbull, Cohen, Bienenstock, & Norman, 1996; Morrison, McNally, Wylie, McFaul, & Thompson, 1996). In general, feedback is the key to turning assessment experiences into learning experiences (Ende, 1983; Pendleton, Schofield, Tate, & Havelock, 1984; Prideaux, 1992).

8.07.4.4 Interdisciplinary Teaching

Much of the input of health psychologists to teaching in other health disciplines occurs in cooperation with multidisciplinary teams. Therefore flexibility about other perspectives and a capacity for constructive teamwork can be presented to students as part of showing what psychology understands and can offer to teach. Material on roles, group dynamics, and the social psychology of power and influence is all relevant.

8.07.4.5 Applying the Principles of Permanent Behavior Change

The psychosocial aspects of health and health care can seem irritatingly vague and complex to students who are more familiar with the clarities of the early stages of physical sciences. Health psychologists therefore need to make concrete for them how the psychosocial and physical are interdependent and how patient response to treatments is a subtle combination of both (as summarized for example by Cohen & Rodriguez, 1995). Because of its long association with education and its particular skills in understanding and producing behavior change, psychology should be well-placed to facilitate the permanent learning which is required.

The aim is to achieve long-term learning which will last students not just to the end-of-year exam but for the duration of their professional working lives. Hopefully they never develop undesirable habits such as adopting an exclusively biomedical focus or inattentive, unresponsive communication styles. However as with children beginning to smoke cigarettes, bad influences may emanate from peers and from prestigious models. To maintain learned changes over long periods of time, the natural agents of reinforcement must replace the psychologist; in other words other faculties than health psychology must encourage the application of health psychology knowledge and skills, and eventually the application of these in practice must become self-rewarding. Continuing on-the-job training or retraining ("booster sessions") are likely to be valuable, especially once gaps in knowledge and skills have become apparent to workers or their supervisors.

The "stages of change" model (Prochaska, DiClemente, & Norcross, 1992) from the behavior change literature shows that it is not worthwhile to attempt behavior change with people who have not committed themselves to make the change. Analogously perhaps, there is no point in advocating health psychology learning until students see its relevance. Thus the ground needs to be prepared by showing its usefulness to their future work. In early stages of education careful planning is needed to do this within a largely nonpracticing environment for the students. A long-term perspective is needed when health psychologists begin to try to influence other professions; fortunately other health professions have shown receptivity to psychological perspectives for some time now.

One way to facilitate the integration of health psychology knowledge and professional applications as early in the course as possible, is to engage in co-teaching with high-status practitioners of the discipline in question. Health psychologists working in clinical settings also present valuable teaching opportunities. Another way to encourage retention of undergraduate learning is to make explicit its role as a foundation for health psychology components of postgraduate masters and doctoral courses and entrance exams for specialist colleges.

8.07.5 CONTENT

Health psychology ranges in the size of its unit of analysis from the culture and norms of large community groups and institutions to individual neuroendocrines, and obviously different aspects of the subject will be of greatest interest to different disciplines. Also, the relevance of parts of health psychology knowledge may depend on the setting in which students of other disciplines will mostly practice, such as the large institution (e.g., hospital or corporation), in the community, or in a solo or small-group practice/business. Nonetheless certain common themes occur in the work of all health professionals, and these are centered on the whole person level of analysis. Some such common topics across disciplines, where health psychology has a large teaching contribution to offer, are listed below.

For reasons of space and duplication, this chapter cannot offer exhaustive references. Readers are referred to excellent reviews in other chapters in this volume, where experts provide comprehensive surveys of health psychology knowledge about 22 kinds of health problems. Resource books in health psychology include those by Jospe, Nieberding, and Cohen (1980), King and Remenyi (1986), Harvey (1988), Johnston and Marteau (1989), Bennett, Weinman, and Spurgeon (1990), Taylor (1995), Pitts and Phillips (1991), Brannon and Feist (1992), Sarafino (1994), Steptoe and Wardle (1994), and Broome and Llewelyn (1995). Key periodical sources of timely research reports and reviews include *Health Psychology*, *Psychology and Health*, *Psychology, Health and Medicine*, the *Journal of Health Psychology*, the *British Journal of Health Psychology*, the *Journal of Occupational Health Psychology*, *Social Science & Medicine*, behavioral medicine journals, and clinical, social, and organizational psychology journals. Papers with health psychologist authors also appear regularly in the psychiatric, general practice/primary care, public health, and health services administration journals.

Obtaining mastery of the Medline and other computerized data retrieval systems, and of the Internet, are highly desirable skills for educators. As libraries are forced to reduce their journal subscriptions, many seem to be more willing to obtain photocopied articles from sister institutions, sometimes by facsimile. Information technology improvements are of critical value for health psychologists as for other academics, since nobody can expect that their own colleagues or contacts will be able to provide a comprehensive picture of the state of current knowledge in this rapidly expanding field. National and international conferences abound, and there are numerous newsletters, seminars, and workshops sponsored by scientific and professional societies (some with multidisciplinary membership) with interests in health psychology.

The broad goals of introducing health psychology to the curricula of other health professions were outlined in Section 8.07.3, with a selection of references. The following checklist therefore summarizes the specific topics which health psychologist teachers and trainers in other disciplines may find useful to include in their courses.

8.07.5.1 Topics About Health and Illness

Health. The definition and measurement of health; how people assess their own state of health and decide how to proceed; comorbidity of psychological and physical distress; how health beliefs and practices can be changed by educational campaigns in order to promote health and prevent illness; genetic screening and counseling and their ethical implications.

Stress. How physical well-being is affected by chronic stress or anxiety, and how such effects can be prevented or reduced; the role of coping strategies and social supports; acute stress arising from invasive or painful procedures and how to reduce patients' suffering and hasten their recovery; psychological responses to chronic illnesses and disabilities, including in family caregivers.

Pain. This includes chronic pain and headaches; its determinants and management by psychological methods.

Aging. The stages of human cognitive and psychosocial development through life, including the challenges and vulnerabilities typical of each age group, and the influences of sex, social class, and cultural background; how people respond to loss and bereavement, including how they can be helped to face their own death or that of loved ones.

Risk factors. Sociocultural and behavioral risk factors for various illnesses; special needs of women, children, the elderly, handicapped, ethnic minorities, homosexuals, and the unemployed.

Referral. When and how to make referrals to local clinical health psychologists for problems outside the other discipline's own area of expertise.

8.07.5.2 Topics About the Interaction Between Health Professional and Patient

Roles. The roles of professional help-provider and help-seeker, and the dynamics of power and influence between the two parties; roles within health care teams and institutions; decision-making about health care services and resources.

Communication. The mechanisms of effective communication between the professional and patient with their differing amounts and kinds of knowledge and differing expectations; techniques for the specially demanding communication tasks such as giving bad news or dealing with "difficult" patients; informed consent and ethical relations with clients.

Adherence. The nature and reasons for patient nonadherence to professional recommendations, and how nonadherence can be reduced or at the least, explored and taken into account.

Behavior change. Attitude and behavior change and how to influence health-relevant behaviors such as smoking, alcohol and drug use, unsafe sex, weight, diet, and exercise; other behavioral interventions such as biofeedback, relaxation training, and postaddiction relapse immunization; worksite stress management. Other psychological treatments including counseling for psychosocial problems and preparation for surgery and hospitalization.

Placebo effects. The powerful nonspecific healing effects of hope and trust, and how these can be both maximized in practice and taken into account in evaluating treatments.

Burnout. The psychological hazards of work in human service professions, and how helping professionals may notice and deal flexibly with the particular stressors which arise (for them and for colleagues) from their work.

8.07.6 IMPLICATIONS AND CONCLUSIONS

This final section gives consideration to the implications for health psychology and health psychologists, of their participation in the teaching and training of other disciplines.

8.07.6.1 Needed Attributes of Health Psychologists who Teach Other Professions

The credible teacher of health psychology to students in other health disciplines should have a sound training in psychological research, ideally some experience in health care settings as researcher or clinician, and in a perfect world, pedagogic skills too. There may however be some delays until many such people are available. In the current economic climate of higher education there is likely to be a cyclic relationship between the availability of employment positions for health psychologists, and the diversion of resources to develop training programs in health psychology. Specific professional training in health psychology is becoming available, and opportunities for practice will increase with recognition of the health psychologist's contribution and corresponding financial support from hospitals and insurers (Diekstra, 1991; Friedman, Sobel, Myers, Caudill, & Benson, 1995).

Psychologists who accepted pioneering positions in health faculties from the 1960s were rewarded for venturing outside the mainstream of academic psychology, by opportunities for collaborative research with other health professionals and correspondingly, chances to advance the discipline of health psychology. A bootstrapping process then meant that opportunities also arose for clinical work with cardiologists, oncologists, pediatricians, community nurses, general practitioners, and many other health professionals, again with advantages for the development of the discipline. However questions are now being raised about the long-term consequences of health psychologists sharing their expertise with others, which will be discussed below.

8.07.6.2 Needs of Health Psychologists who Teach Other Professions

Information about the other professions' traditions, expectations, practice patterns, and needs should be readily available from teaching colleagues and associated practitioners. This will give a vital flavor of reality to the teaching examples and assignments used.

Health psychologists who teach nonpsychology students may also need peer support. Recognition and feedback from nonpsychologist teaching colleagues would be very welcome, but it may be valuable to use professional societies and their journals or newsletters and conferences to develop networks of people with similar jobs, in order to share information, practical advice, and understanding. Groups with a focus on health psychology within the professional societies include Division 38 in the American Psychological Association, a special group within the British Psychological Society, a section in the Canadian Psychological Association, a college within the Australian Psychological Society, and a division in the International Association of Applied Psychology. In addition there is an Association of Medical School Professors of Psychology, a European Health Psychology Society, an International Society for Health Psychology, and doubtless other national and international organizations. As noted above, the Internet, and the national societies for health informatics (information technologies applied to health-related knowledge) with their conferences, newsletters, and e-mail discussion groups, greatly increase the opportunities for connection with health psychology teachers around the world.

8.07.6.3 Consequences for Health Psychology of Teaching Other Professions

Some of the advantages to individual health psychologists of involvement in teaching other disciplines have been outlined above. Opportunities for joint research with a wider subject pool help with physiological measures such as blood assays, immune function tests, and cardiovascular health and access to funds for health and medical research can all advance individual careers as well as the discipline itself. The experience gained in other disciplines and settings could also very valuably supplement teaching to psychology students. However some doubts have been expressed about psychologists being prepared to share their knowledge and especially their skills, with other disciplines (Frank & Ross, 1995; James, 1994; Richards, 1994).

Often psychological content is not explicitly recognized as such, in teaching materials for other disciplines. For example in one health-oriented nursing text (Clark, 1986), there is considerable information about how to change behavior by collecting baseline data, deciding what reinforcers are relevant, goal-setting and behavioral contracts. Yet the only reference to psychology in the index is to an explanation of the field of psychoneuroimmunology (immediately after the section explaining reflexology). Similarly a popular textbook in occupational therapy (Kielhofner, 1992) refers to the theory of behavior modification as being a contribution from the related field of psychology which is sometimes useful in occupational therapy practice; yet does not mention the contribution of psychological research to our understanding of group dynamics and group therapy, a field where occupational therapists feel themselves to have a major role (Gibson, 1990; Howe & Schwartzberg, 1986).

A similar lack of recognition for the role of health psychology has been notable in health insurers and health management organizations. Unless health psychology can establish its unique role in providing cost-effective health care, and provide sufficient numbers of trained practitioners, there are fears that physicians (of whom for the first time there may soon be an oversupply), nurses, social workers, occupational therapists, and others may step in to fill the gap (Frank & Ross, 1995; Swerissen & Foreman, 1991).

At the 1996 Convention of the American Psychological Association, Cynthia Belar, the current President of Division 38 (Health Psychology) gave an address entitled "Clinical health psychology: A specialty for the twenty-first century" in which she encouraged health psychologists to place public welfare above "guild issues," and to continue to cooperate with other health professions. Mutual respect and recognition amongst health professions, with due credit for discipline-specific skills and lack of encroachment, are goals to which health psychologists may aspire. Health care and psychology's role within it will benefit from efforts to share psychological knowledge and some basic skills; future expansion of health psychology will follow from widening recognition of psychologists' value as consultants and collaborators in the processes of health-related diagnosis, treatment, prevention, and research. Health psychologists who teach in other health disciplines thus have a crucial role in demonstrating to those future practitioners, the value of our discipline and profession.

8.08.1 INTRODUCTION

Chronic diseases of the cardiovascular system, which include coronary heart disease (CHD) (also known as ischemic heart disease or atherosclerotic heart disease), high blood pressure, and stroke, constitute a major public health problem and the leading cause of death in Western countries (Higgins & Luepker, 1988; National Heart, Lung, and Blood Institute [NHLBI], 1994). Many physiological, environmental, and behavioral variables interact in the development of these disorders. For example, many of the causal agents for CHD can be modified, relate to habits of living, and are under the control of the individual. It can therefore be said that CHD is a disorder that is a result of the individual's lifestyle, and it is not surprising that cardiovascular diseases have been among the most widely studied topics in health psychology (e.g., Baum, Gatchel, & Krantz, 1997; Krantz, Grunberg, & Baum, 1985).

Over the past 30 years in the USA, there has been encouraging news that death rates from heart disease have been decreasing (NHLBI, 1994). Through the use of epidemiologic and statistical analyses these changes have been attributed partly to dramatic medical developments such as drugs and improvements in medical technology, but also to awareness by the public of behaviors that are risk factors, and attempts by individuals to modify components of lifestyle that constitute risk factors for heart disease (Higgins & Luepker, 1988). Goldman and Cook (1988), for example, used the epidemiologic literature to estimate that about 40% of the reduction in cardiovascular mortality was due to improvements in medical care, such as drug treatments for high blood pressure and improvements in cardiac care. However, more than half of the decline in death rates from CHD (54%) could be attributed to lifestyle changes, such as changes in fat consumption and reductions in cholesterol levels (30%) and cigarette smoking (24%). These data reinforce the important link between individual lifestyle and risk of coronary disease. Because of space limitations and the vastness of the available literature, this chapter gives a selective overview of behavioral science contributions to understanding the etiology and treatment of two of the major cardiovascular disorders: CHD and essential hypertension. For comprehensive reviews of various aspects of this vast literature, the reader is referred to Allan and Scheidt (1996), Dubbert (1995), Julius and Bassett (1987), Ockene and Ockene (1992), Shumaker and Czajkowski (1994), and Siegman and Smith (1994).

8.08.2 CORONARY HEART DISEASE

8.08.2.1 Overview of Pathophysiology

Coronary atherosclerosis is a condition that results when the coronary arteries, which deliver blood to the heart, become narrowed by fatty deposits called plaques. Ischemic heart disease refers to a set of conditions thought to result from coronary atherosclerosis. Myocardial ischemia—the inadequate flow of blood to cardiac tissue—results when arterial narrowing can cause insufficient blood supply to the heart. Ischemia, in turn, can sometimes be accompanied by chest pain—a condition called angina pectoris. Severe or repeated myocardial ischemia also predisposes the heart to life-threatening disturbances of cardiac rhythm, which can result in sudden cardiac death. A heart attack, or myocardial infarction (MI), results when cardiac tissue dies because arterial plaque becomes unstable and a complete blockage occurs, or when ischemia becomes prolonged or severe.

8.08.2.1.1 Standard risk factors for CHD

Based on a set of so-called "standard" risk factors, individuals who are likely to develop CHD can be identified with a moderate degree of accuracy. When multiple risk factors are present in the same individual, the CHD risk increases multiplicatively with the addition of each risk factor (Higgins & Luepker, 1988). Several of the coronary risk factors cannot be modified directly. These include chronological age, sex, race, and a strong family history of coronary disease.

With aging, there is a greater likelihood of developing heart disease, and nearly half of all coronary victims are aged over 65 years. Especially at younger ages, males are at greater risk of CHD than are females. The lower risk in women at younger ages is in large part attributable to a protective effect of estrogens (Lerner & Kannel, 1986). Thus, gender differences in coronary disease become much less pronounced as women reach menopause, and exogenously administered estrogens lower the risk of CHD in postmenopausal women. Also, in the USA, blacks are more prone to CHD than whites. This may be related to the fact that blacks are much more susceptible to high blood pressure, with high blood pressure being a major CHD risk factor. Another nonmodifiable risk factor is family history. Susceptibility to CHD at an early age appears to be transmitted genetically, and certain families are at higher risk than others (Glueck et al., 1985; Nicolosi & Schaefer, 1992). However, even if individuals fall into the higher risk groups because they possess the nonmodifiable risk factors, they can still minimize their risk by modifying other coronary risk factors that are amenable to change.

Modifiable risk factors for coronary disease include essential hypertension, cigarette smoking, high blood levels of low density lipoprotein (LDL) cholesterol and low levels of high density lipoprotein (HDL), diabetes, obesity, and sedentary lifestyle (Ockene & Ockene, 1992). (We discuss the so-called "psychosocial risk factors" in Section 8.08.2.2). For example, cigarette smoking is a preventable behavior, and the death rate from MI is markedly higher among smoers compared to nonsmokers. However, for those who give up the habit, the death rate begins to decrease almost to the level of those who have never smoked (Higgins & Luepker, 1988). Essential hypertension, or chronic high blood pressure, is also an important risk factor for the development of CHD that can be modified via pharmacological or behavioral means (see Section 8.08.3).

It should be noted that there is still some controversy as to the relative importance of such factors as diet and exercise in the development of coronary disease. For example, although large reductions in dietary intake of saturated fats and cholesterol have been shown to slow the progression of CHD (e.g., Ornish et al., 1990), several studies have not found that dietary patterns within the population are predictive of later development of heart disease (Mann, 1977). Generally, the least controversial and most widely accepted risk factors are considered to be smoking, high LDL and low HDL serum cholesterol levels, and high blood pressure (Kannel, 1979).

8.08.2.2 Psychosocial Risk Factors for CHD

Despite extensive research into the standard physiological risk factors, the best combinations of these factors still do not account for the occurrence of heart disease in many individuals (Jenkins, 1983). Thus, the search has been broadened to examine potential new risk factors, including social and psychological characteristics, and characteristics of the environment. In this chapter we discuss four areas of research on cardiovascular disorders:

(i) chronic and acute stress and factors such as social support that can moderate the effects of stress on cardiovascular pathology;

(ii) personality traits, such as hostility, anger, and type A behavior, which may be risk factors for CHD;

(iii) depression, which can lead to poor prognosis in cardiac patients; and

(iv) individual differences in physiologic reactivity (responsiveness) to behavioral stressors.

8.08.2.2.1 Stress and CHD

Among the lay public, it is widely believed that acute and chronic stress play a role in the onset of CHD manifestations such as MI and sudden cardiac death. Until recently, this view was corroborated primarily by anecdotal and case reports, some epidemiological research (Engel, 1971; Myers & Dewar, 1975), and human and animal studies demonstrating physiologic and pathophysiologic effects of mental stress on the cardiovascular system (Kamarck & Jennings, 1991; Manuck, Marsland, Kaplan, & Williams, 1995). An increased interest in the role of stress as a trigger of clinical cardiovascular events has been fostered by evidence suggesting that, in susceptible patients, acute cardiovascular events (e.g., MI, cardiac ischemia) are frequently triggered by activities such as physical or mental stress, rather than occurring spontaneously (Muller, Tofler, & Stone, 1989). In addition, studies making use of a variety of current techniques for assessing cardiac function in the laboratory and in the field provide convincing evidence for the pathophysiological mechanisms and effects of behavioral factors as triggers of myocardial ischemia (Deanfield et al., 1984; Gottdiener et al., 1994; Krantz et al., 1996; Rozanski et al., 1988).

The effects of chronic stress on coronary disease have been studied by assessing psychological and social conditions at work and in other life domains (e.g., home and family). In addition, useful animal behavioral models of coronary disease have been developed and utilized. Research on the role of behavior in the development of coronary artery disease has revealed that the effects of stressful situations on physiology and behavior depend on psychological and contextual factors. If situations (e.g., the workplace) are not viewed or interpreted as harmful, threatening, or challenging, they can produce smaller and even an absence of adverse physiologic responses (Lazarus & Folkman, 1984). Therefore, the relationship of various psychological and social stresses (e.g. occupational conditions) to CHD seems to depend on the meaning of the situation to the individual, and the way in which individuals perceive their life situations (Cohen, Evans, Stokols, & Krantz, 1986).

8.08.2.2.2 Animal studies of stress and atherosclerosis

In recent years, a particularly important series of studies in this area have been conducted at the Bowman–Gray School of Medicine (Kaplan & Bush, 1982). They used cynomolgus monkeys, whose coronary disease pathology closely resembles that of the human condition in these animals. In addition, many of the prominent aspects of their behavior, such as forming a social hierarchy, competition, and aggression, are salient aspects of human behavior analogous to those which have been implicated as potential contributors to coronary disease in humans.

The introduction of unfamiliar monkeys into an established social group is a powerful social stressor, leading to increased aggressive behavior as group members attempt to re-establish a social dominance hierarchy (Manuck, Kaplan, & Matthew, 1986). These stressful conditions were created by periodically reorganizing social groups (the "unstable" condition). Unstressed animals in "stable" social conditions were assigned to similarly sized groups having fixed memberships over the duration of the study (Kaplan & Bush, 1982). Based on the patterns of their behaviors in the groups, monkeys were categorized as either dominant or subordinate.

In one study of male monkeys, the dominant animals in the unstable social condition developed more extensive coronary atherosclerosis than their subordinate counterparts. However, differences were less evident between dominants and subordinates in the stable social condition—under stable social conditions, dominants were slightly less affected than subordinates. Providing a clue as to the possible behavioral reasons for the development of disease, dominant animals in the unstable condition showed the most aggression toward other animals and a disruption of positive social interactions. In another study conducted with female monkeys, subordinate animals developed greater coronary artery disease than dominants (Kaplan, Adams, Clarkson, & Koritnick, 1984), and as in the other studies with male animals, these effects could not be attributed to the physical risk factors. Reproductive function in many of the subordinate animals was also disrupted, and these behaviorally induced reproductive problems may have lessened these animals' "protection" against coronary disease.

In summary, experiments with nonhuman primates have demonstrated a causal effect of psychosocial stress in the development of coronary artery disease. Interestingly, the specific effects of stress depend on individual characteristics (e.g., level of dominance) that determine how objective conditions will affect each animal's behavior. Interestingly, the particular traits in animals (e.g., dominance and aggression) that relate to risk of atherosclerosis foreshadow similar findings obtained in human populations.

8.08.2.2.3 Occupational stress

Research on occupational stress and health has sought to determine which occupations are most stressful and the particular characteristics of occupations that lead to elevated risk of coronary disease (Karasek & Theorell, 1990). In this regard, several characteristics of settings and of individuals have been identified that potentially can be modified to reduce stress. Working conditions that have been associated with CHD risk include the psychological demands of the job, autonomy on the job (how much input a worker has in making decisions), and satisfaction on the job. Job demands refer to job conditions that tax or interfere with the worker's performance abilities, such as workload and work responsibilities. Level of job autonomy or control refers to the ability of the worker to control the speed, nature, and conditions of work. Job satisfaction includes gratification of the worker's needs and aspirations derived from employment (Wells, 1985).

Low levels of control over one's job and excessive workload seem to be a particularly important combination in heightening job-related stress. Karasek and colleagues (e.g., Karasek & Theorell, 1990) proposed that conditions of high work demands combined with few opportunities to control the job situation (low decisional latitude) are associated with increased coronary disease risk. Conditions of high demand and low control are called "high strain" situations. The Karasek "job demand/control" hypothesis has been tested in several populations by applying a "job characteristics scoring system" based on responses to several national surveys of workers. These job characteristic scores can distinguish between occupations along the dimensions comprising job strain. The job strain model has shown the ability to predict cardiovascular disease and mortality in studies of male Swedish workers, and in studies of men and women in the USA (Karasek & Theorell, 1990; Karasek et al., 1988; Schnall, Devereux, Pickering, & Schwartz, 1990). However, a recent longitudinal study of patients who underwent diagnostic testing for coronary disease did not find that occupational stress was related to extent of disease in this population or to subsequent cardiac morbidity or mortality (Hlatky et al., 1995). These negative findings may be attributable to the fact that the study group consisted of a selected group of largely symptomatic patients, and the effects of job strain may be obscured in such a population.

A study of occupational stress and CHD among women also suggests that the relationship of job conditions to coronary disease depends on the individual's work and family demands, and their control over these situations. Haynes and Feinleib (1980) analyzed data from the Framingham Heart Study, a major epidemiologic study of heart disease conducted by the National Institutes of Health. They asked the question of whether the increasing employment of women outside the home has adversely affected their cardiovascular health. In the mid-1960s, middle-aged women were examined for the development of CHD for the ensuing eight years. Working women, that is women who had been employed outside the home for more than half their adult years, were compared with housewives and with men. The results indicated that working women in general were not at significantly higher risk of subsequent coronary disease than housewives. However, clerical workers (who perhaps have low job control), and working women with children (who have high family demands) were more likely to develop CHD, as were women whose bosses were nonsupportive. Interestingly, the likelihood of CHD increased linearly with the number of children for working women, but not for housewives (Lacroix & Haynes, 1987).

8.08.2.2.4 Low levels of social support and lack of economic resources as CHD risk factors

Certain aspects of the social environment, particularly social isolation, low social support, and lack of social and economic resources can also increase an individual's risk of cardiovascular disease (Shumaker & Czajkowski, 1994). Social support refers to the instrumental, emotional, and informational aid obtained from an individual's social ties and community resources (Cohen & Wills, 1985). It has been hypothesized that social support may serve as a buffer or moderator between life stressors and cardiovascular disease outcomes. On the other hand, the absence of tangible aid from a supportive social network may also have direct adverse effects on health, for example, by impeding access to needed help or interfering with medical compliance. In studies in the USA and other countries, people with strong social networks are at a relatively lower risk of developing CHD (Shumaker & Czajkowski, 1994).

In industrialized societies, rates of cardiac morbidity and mortality are inversely related to socioeconomic status, with disease rates higher among poorer individuals. The inverse association of CHD mortality with socioeconomic level cannot be explained by different use of medical care services by individuals in lower socioeconomic groups (Marmot, 1983). Although it is known that the prevalence of standard CHD risk factors (e.g., high blood pressure and smoking) decreases with increasing socioeconomic status, this is not sufficient by itself to explain all the increase in coronary mortality attributable to low socioeconomic status.

Low social support and lack of economic resources appear to increase interactively the risk of adverse prognosis in CHD patients. Ruberman, Weinblatt, Goldberg, and Chaudhary (1984) (Figure 1) demonstrated that level of education and social support resources (elements associated with socioeconomic level) are significant factors affecting the survival of men after a first MI. In this study, men with low educational levels were likely to experience more isolation and life stress than were men with higher levels of education. Low education men had mortality rates twice as high as men with more education and social support. More recently, two studies demonstrated that living alone led to a near doubling of the risk of recurrent heart attack and death in post-MI patients, and that, independent of other prognostic medical factors, unmarried male and female coronary artery disease patients without a confidant and patients with low household incomes were at increased risk of cardiovascular death over a five-year period (Case, Moss, Case, McDermott, & Eberly, 1992; Williams et al., 1992). Social factors presumably influence prognosis by influencing patients" psychological reactions to MI. For example, the poorly educated may be at increased risk of job loss following an infarction, and for those who live alone the future may be even more bleak.

8.08.2.2.5 Acute stress and anger as cardiac disease triggers

As opposed to focusing on chronic social and environmental conditions, a relatively new research area has focused on the role of acute stress and of emotions as triggers of the onset of coronary artery disease manifestations in individuals with pre-existing disease (see Krantz et al., 1996; Muller et al., 1989). Earlier studies observed that stressful life events, such as death of a spouse, occurred in the 24 hours preceding death among patients who died suddenly from coronary disease (e.g., Cottington, Matthews, Talbott, & Kuller, 1980; Myers & Dewar, 1975) and that loss events (e.g., death of a loved one) occurred to sudden death victims more

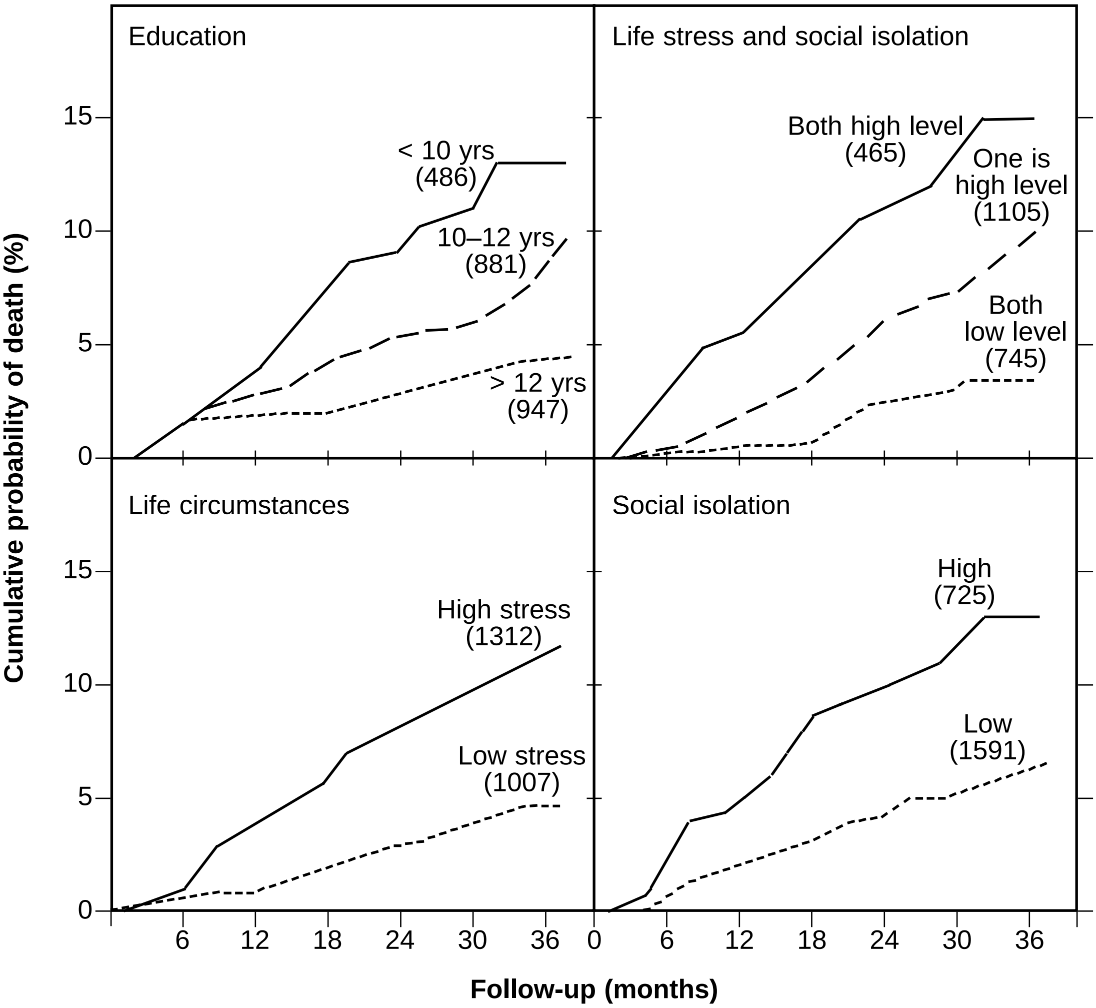

Figure 1 The effect of social factors on the survival of men after a first MI.

frequently than to controls. These studies corroborated earlier findings (e.g., Parkes et al., 1969) that observed a 40% increase in cardiovascular mortality among widowers. However, these and related studies are subject to the criticism of biased recall of stressful events by relatives or friends of sudden death victims, who served as informants in these studies.

The occurrence of disasters and personal traumas has also been related to an increase in cardiac deaths and increased rates of MI. For example, during the Iraqi missile attacks on Israel during the initial days of the 1991 Gulf War, there was a significant increase in fatal and nonfatal cardiac events among the population living close to Tel Aviv (Meisel et al., 1991). Cases of acute MI treated in the intensive care unit of a Tel Aviv medical center were elevated during the week following the missile attacks (January 17–25, 1991), compared to the week prior to the attacks and to an index period consisting of the same week a year earlier (Figure 2). In addition, there was an increase in the sudden death rate during January 1991 compared with the same period a year earlier. Mortality statistics among the entire Israeli population during period showed that on the day of the first missile strike, excess mortality observed was greater among women than among men (Kark, Goldman, & Epstein, 1995). This increase in cardiovascular mortality occurred largely in the Tel Aviv area where the missile attacks occurred.

Mittleman et al. (1995) used a novel epidemiologic methodology that compares each patient's activities before MI with his or her usual levels of activities, in order to assess the immediate physical and mental triggers of onset of heart attack. In a study of patients interviewed a median of four days after MI, 2.4% reported episodes of anger within the two hours prior to onset of MI. Following these

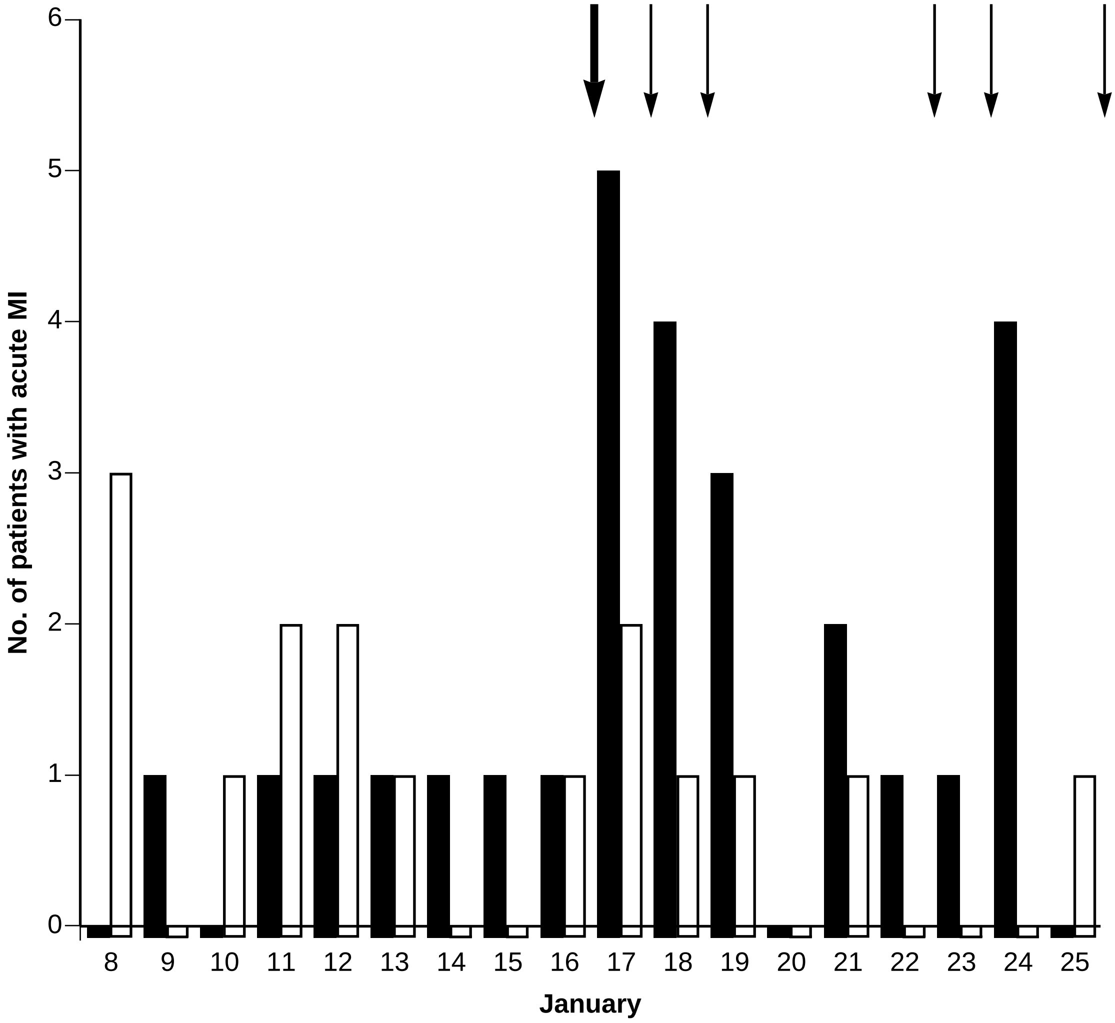

Figure 2 Daily incidence of acute myocardial infarction (MI) observed in Tel Aviv-area coronary care units during the period of the Iraqi missile attacks (January 8–25, 1991) (filled colomns) compared with the same time period in 1990 (unfilled columns) (large arrow = beginning of the Gulf War; small arrows = missile attacks on Israel).

episodes of anger, the risk of MI following episodes of anger was more than twice as high (Figure 3).

8.08.2.2.6 Stress and cardiac ischemia

It is possible to monitor continuously the electrocardiogram (ECG) during daily life in patients with coronary disease in order to detect the occurrence of cardiac ischemia—the inadequate supply of blood to the heart that is a clinical manifestation of coronary heart disease activity. In several studies, mental and physical activities of cardiac patients undergoing ambulatory monitoring of the ECG have been assessed using structured diaries. During daily life, ischemia in these patients is accompanied by strenuous physical exercise relatively infrequently, the majority of such episodes occurring during normal daily activities (e.g., Schang & Pepine, 1977). Mental stress and emotion also appear to be potent triggers of daily life ischemia in coronary patients (Barry et al., 1988; Gabbay et al., 1996). For example, Gabbay et al. (1996) assessed the effects of specific emotions on ischemia by using a more sophisticated diary in patients undergoing ambulatory monitoring. Ischemia occurred most frequently during moderate intensity physical and mental activities. Patients spent the largest proportion of time engaged in low intensity physical and mental activities, but the likelihood of ischemia was greatest during intense physical activities and during stressful mental activities. The percentage of time in ischemia (5% of the time) was approximately equivalent for high-intensity physical (Figure 4(a)) and high-intensity mental activities (Figure 4(b)), compared with 0.2% of

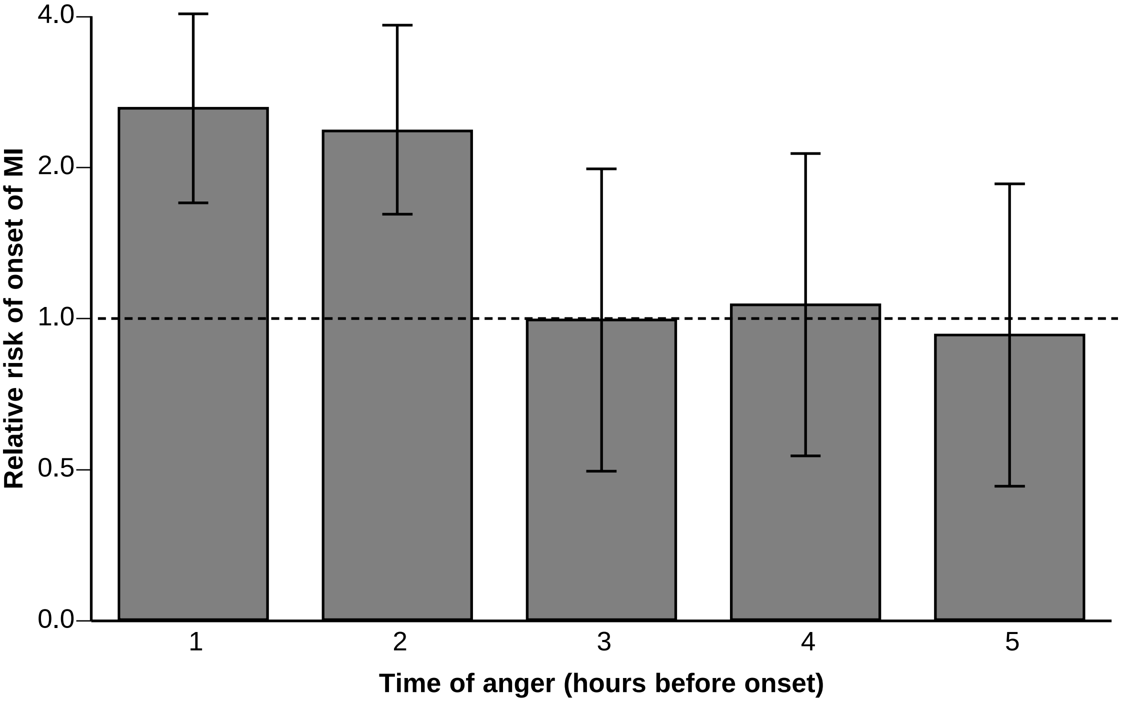

Figure 3 Episodes of anger and the relative risk of MI.

the time when patients were engaged in low intensity activities (see Figure 5).

Strenuous physical activity (e.g., walking) and the experience of intense anger were potent ischemic triggers.

Studies have also utilized a variety of sensitive means to evaluate the effects of mental stress on myocardial ischemia in the laboratory, enabling investigators to infer causal relationships between stress and ischemia and to assess physiologic and psychological mechanisms responsible for these effects. These studies have revealed that laboratory mental stressors can provoke ischemia in a substantial subset of patients with coronary artery disease (e.g., Blumenthal et al., 1995; Deanfield et al., 1984; Goldberg et al., 1996; Gottdiener et al., 1994; Rozanski et al., 1988). Ironson et al. (1992) further reported that an anger-inducing stressor was a particularly potent psychological stressor in its ability to trigger ischemia.

8.08.2.2.7 Summary

In summary, there is evidence that both acute and chronic stress may either promote the development of or trigger CHD events. Key aspects of chronic stress that are potential risk factors for cardiac events and that can potentially be modified include job strain and, particularly among cardiac patients, low social support and lack of economic resources. Converging evidence also suggests that anger is an emotion that is a potent trigger of cardiac events such as ischemia or infarction. In addition to these environmental and social factors, several individual behavioral traits are reviewed below that have been suggested as CHD risk factors.

8.08.2.3 Individual Characteristics as CHD Risk Factors

8.08.2.3.1 Type A behavior: current status

The concept of a coronary-prone personality—a set of emotions, behaviors, and personality attributes that characterize people who are likely to develop CHD—has origins as far back as a century or more ago. During the 1950s, cardiologists Friedman and Rosenman (1959) described the type A behavior pattern (TABP), characterized by excessive competitive drive, impatience, hostility, and vigorous speech characteristics. A contrasting behavior pattern, called type B, consists of the relative lack of these characteristics and a more easygoing style of coping. Friedman and Rosenman (1974) developed a structured interview to measure type A behavior based on the presence of observable behaviors such as speech characteristics and the manner in which subjects respond to questions, rather than relying on whether subjects describe themselves as impatient,

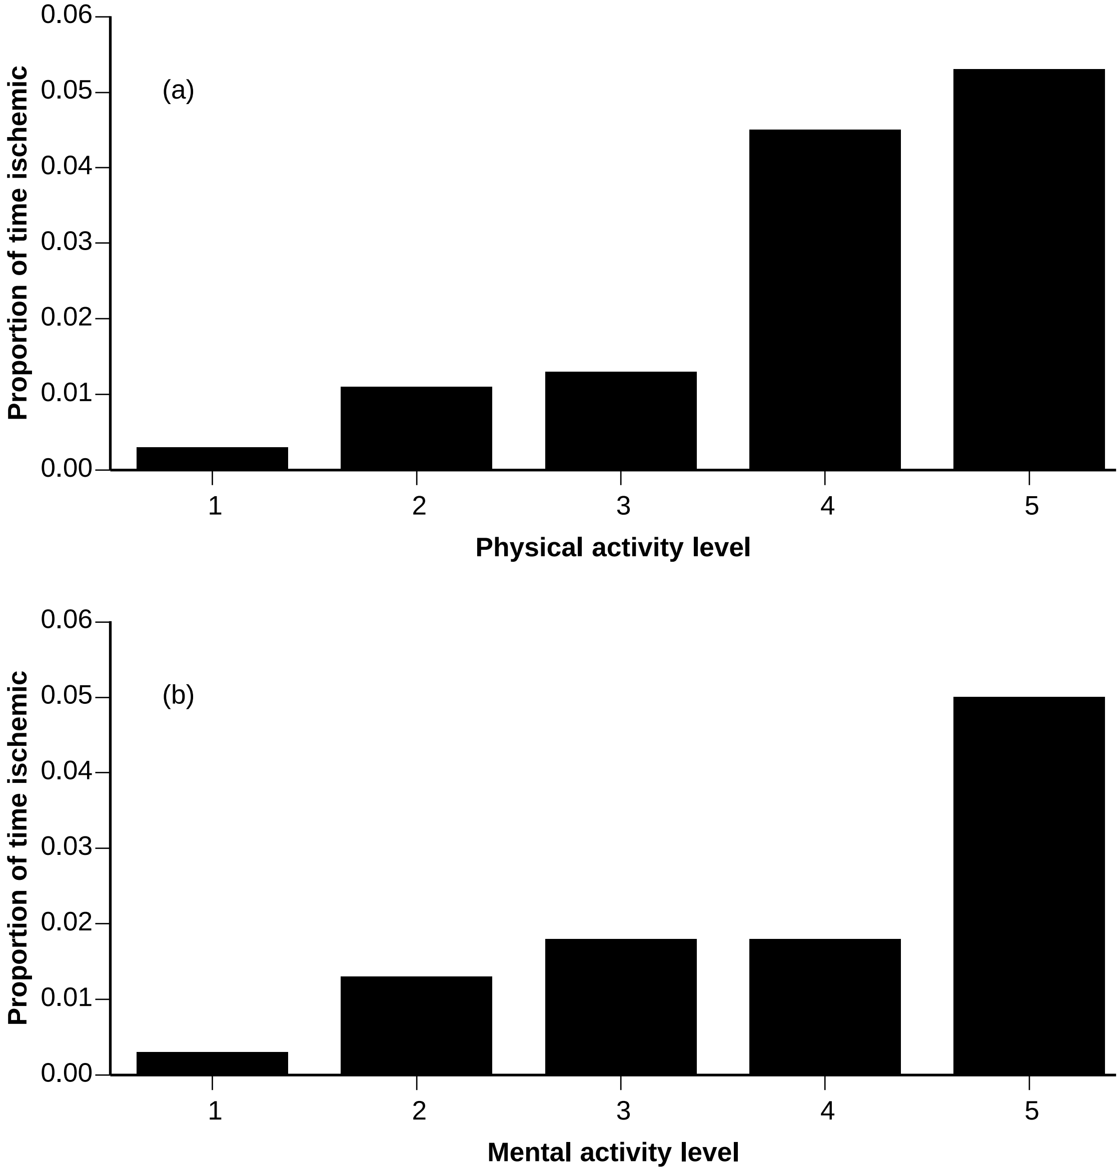

Figure 4 The percentage of time in ischemia at different physical and mental activity levels (adjusted for the time spent in the activity level).

competitive, etc. In contrast to the structured interview, several questionnaire measures developed to assess type A behavior, such as the Jenkins Activity Survey (JAS; Jenkins, Zyzanski, & Rosenman, 1971), relied solely on subjects" self-reports of their own behavior (Matthews & Haynes, 1986), and have generally shown a weaker relationship to CHD than interview-derived type A measures.

Most studies conducted in the 1960s and 1970s to examine the relationship of type A behavior to heart disease revealed a positive correlation between TABP and risk of CHD in men and women, which was both comparable to and independent of the effects of risk factors such as smoking and hypertension. For example, evidence supportive of type A as a risk factor included two major studies of initially healthy individuals. The Western Collaborative Group Study (WCGS) examined over 3000 men for 8.5 years. Those men assessed as type A by interview and questionnaire at study intake were more likely to have developed heart disease over the course of the study compared to type B men (Jenkins, Rosenman, & Zyzanski, 1974; Rosenman et al., 1975). In the Framingham Heart Study, type A behavior was a predictor of CHD among men in white collar occupations and in women working outside the home (Haynes, Feinleib, & Kannel, 1980).

However, since the 1980s, most studies have failed to find a relationship between type A behavior and coronary disease (see Matthews & Haynes, 1986). For example, the Multiple Risk Factor Intervention Trial (MRFIT) was a study conducted to determine whether interventions to modify coronary risk factors such as smoking, high cholesterol levels, and high blood pressure in high-risk men would lessen the likelihood of coronary disease in these individuals. Measures of type A behavior were obtained for over 3000 MRFIT subjects, who were followed for seven years. Type A behavior, as assessed by the structured interview and by the JAS in this high-risk group was unrelated to incidence of a first heart attack (Shekelle, Holley, & Neaton, 1985). This study, then, failed to support a link between type A behavior and heart disease. In addition, there were research reports indicating that, after a heart attack, type B patients (and not type A patients) were more likely to die (Ragland & Brand, 1988). Although this finding could be explained in terms of the healthier type A patients being the ones who initially survived their first heart attack, this result clearly presented problems for the notion of type A behavior as coronary-prone behavior.

The reasons for these inconsistent findings for type A behavior are not entirely clear, and some (e.g., Matthews & Haynes, 1986) have suggested that type A behavior might not be a risk factor for certain high-risk groups (as were tested in the MRFIT study). Others have suggested that type A behavior is more likely to be a risk factor in younger, as opposed to older, subgroups (Williams et al., 1988). Nevertheless, it appears that certain components of type A behavior—particularly anger, hostility, and vigorous speech characteristics—have remained correlated with coronary disease even in studies where overall, or "global," type A behavior has not been related to CHD.

8.08.2.3.2 Anger and hostility

As noted above, type A behavior consists of several behaviors, including competitiveness, time urgency, and hostility, yet it is possible that not all these behaviors contribute equally to coronary risk. What have consistently emerged as correlates of CHD in these studies are characteristics relating to hostility, anger, and certain speech characteristics derived from the structured interview, as well as the characteristic of not expressing anger or irritation or "anger-in." For example, a reanalysis of data from the WCGS described above showed that "potential-for-hostility," vigorous speech, and reports of frequent anger and irritation were the strongest predictors of CHD (Matthews, Glass, Rosenman, & Bortner, 1977). Even in the MRFIT study, which was not able to relate type A behavior to CHD, hostility characteristics in MRFIT subjects were associated with increased CHD risk (Dembroski, MacDougall, Costa, & Grandits, 1989).

The Cook and Medley Hostility Inventory (Cook & Medley, 1954), a scale derived from the Minnesota Multiphasic Personality Inventory (MMPI), has been shown in two studies to be related to occurrence of coronary disease. This scale appears to measure attitudes such as cynicism and mistrust of others (Barefoot & Lipkus, 1994). In one study involving a 25-year follow-up of physicians who completed the MMPI while in medical school, high Cook–Medley scores measured in college students predicted incidence of CHD as well as mortality from all causes, and the relationship was independent of the individual effects of smoking, age, and presence of high blood pressure (Barefoot, Dahlstrom, & Williams, 1983) (Figure 5). There is also evidence that low hostility scores are associated with decreased death rates during a subsequent 20-year follow-up of nearly 1900 participants in the Western Electric Study (Shekelle, Gale, Ostfeld, & Paul, 1983). In other studies it was shown that traits of hostility (e.g. assessed in terms of behaviors and attitudes indicative of hostility derived from the type A behavior structured interview) were related to the development of CHD in initially healthy men and in high-risk participants in the MRFIT study (for a review see Helmers, Posluszny, & Krantz, 1994). Subsequent research has further suggested that hostility scores on the Cook–Medley (1954) scale are higher in low socioeconomic status groups, higher in men and non-whites in the USA, and also positively related to the prevalence of smoking (Siegler, 1994). Thus, it is possible to hypothesize that hostility may account for some of the socioeconomic and gender differences in death rates from cardiovascular diseases (Stoney & Engbretson, 1994).

8.08.2.3.3 Clinical depression as a CHD risk factor

In addition to hostility, the presence of other psychological traits can confer increased risk of poor health outcomes among CHD patients, and hence are important to consider as elements of effective cardiac patient treatment and rehabilitation. Signs and symptoms of clinical depression, including fatigue, exhaustion and dysphoric mood, are prevalent among patients with CHD. Moreover, studies have reported that nearly 1 in 5 cardiac patients can be diagnosed as having the signs and symptoms of

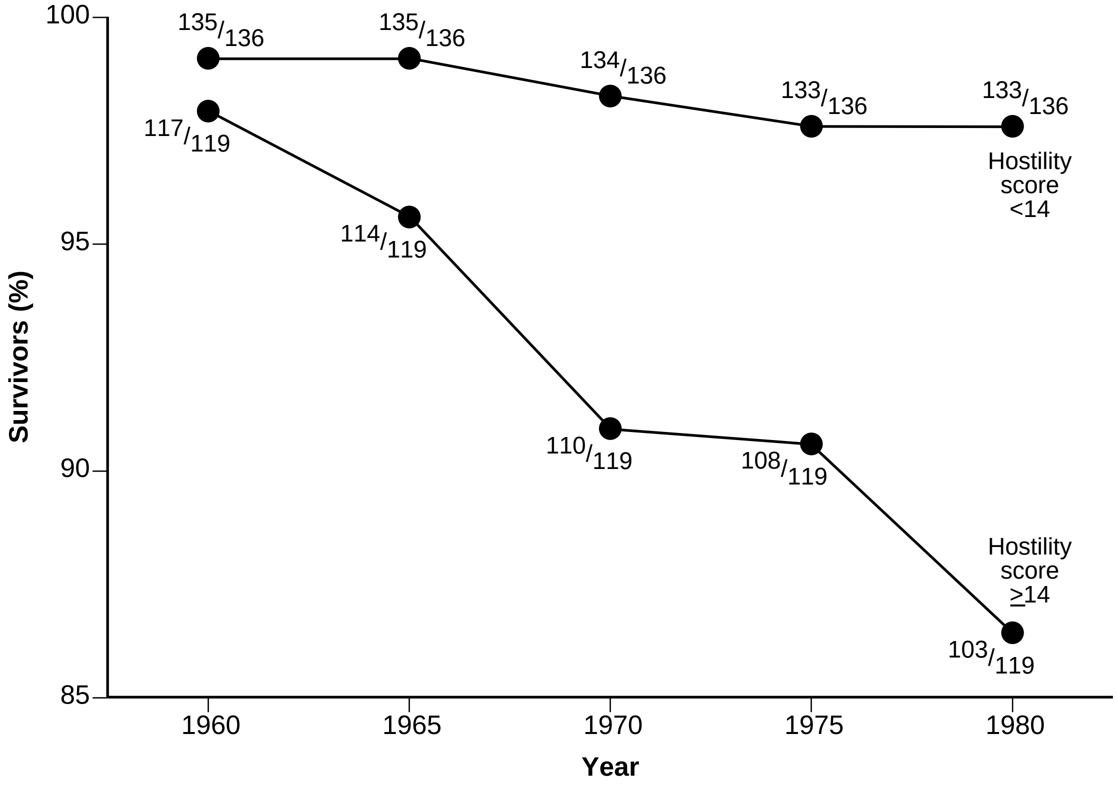

Figure 5 The relationship between hostility score and death rate in the Western Electric Study.

clinical depression (Carney et al., 1987; Frasure-Smith, Lesperance, & Talajic, 1993). However, despite its high prevalence, depression among post-MI patients is often untreated.

The presence of a major depressive episode in CHD patients is associated with poor psychosocial rehabilitation and increased medical morbidity (Carney, Freedland, Rich, & Jaffe, 1995). At least four studies have compared the clinical course of depressed versus nondepressed cardiac patients and noted an increase of events and lower mortality rates associated with depression. Diagnosis of major depressive disorder at the time of coronary angiography was the best predictor of a significant cardiac event (death, reinfarction, bypass, angioplasty) during a one-year follow-up period (Carney et al., 1987). Schleifer, Keller, Bond, Cohen, and Stein (1989) reported a trend toward a higher rate of rehospitalization and reinfarction in depressed patients. Kennedy, Hofer, Cohen, Schindledecker, and Fisher (1987) reported a significant correlation of cardiac arrhythmias, depression, and mortality. Frasure-Smith et al. (1993) prospectively followed 222 post-MI patients and observed that a diagnosis of major depression was a strong predictor of mortality in the 6 months following hospital discharge. In addition, two more recent studies of initially healthy populations have suggested that the presence of a major depressive episode (Pratt et al., 1996) or worsening of depressive symptoms (Wassertheil-Smoller et al., 1996) are prospectively predictive of the subequent development of cardiac events. A parallel set of studies conducted by Appels and colleagues (e.g., Appels, 1990; Kop, Appels, de Leon, de Swart, & Var, 1994) suggest that symptoms of fatigue or exhaustion—even in the apparent absence of clinical symptoms of dysphoria or depressive affect—are predictive of the subsequent development or worsening of cardiovascular symptoms and events. This syndrome of fatigue symptoms has been termed "vital exhaustion" (Appels, 1990). Moreover, evidence suggests that the predictive value of symptoms of fatigue or exhaustion cannot be explained by the effects of illness on mood or energy level (Kop et al., 1994).

To explain the link between depression and/or vital exhaustion, low social support, and mortality in coronary patients, studies have observed reduced compliance with medical therapeutic and exercise regimens in depressed cardiac patients (Carney et al., 1995), and a supportive social network is thought to be necessary to facilitate adequate compliance with medical regimens and reduction of cardiac risk factors (Amick & Ockene, 1994). It has also been suggested that increased susceptibility to cardiac arrhythmias and sudden cardiac death is a mechanism linking major depression to sudden cardiac death in coronary patients (Carney et al., 1995). In addition, recent studies have suggested that the presence of clinical depression can be associated with neural and neuroendocrine responses that predispose to sudden death, and changes in blood-clotting processes that may predispose to coronary thrombosis and to MI (Frasure-Smith, 1991). Research on mechanisms linking depression, social support, and/or lack of economic resources to increased cardiac morbidity and mortality is in its early stages, and this area promises to be a fruitful area for exploration.

8.08.2.3.4 Stress reactivity

The adverse effects of stress on cardiac pathology have been attributed to the neural, endocrine, and cardiovascular effects of stress (Krantz et al., 1996). It has long been known that there are wide individual differences that exist in physiologic reactions to stress, and research suggests that physiological responses (reactivity) to emotional stress may be involved in the development of CHD and/or high blood pressure (see Krantz & Manuck, 1984; Manuck, 1994). The measurement of "reactivity" involves the assessment of cardiovascular and/or hormonal changes in response to stress—not just resting levels of physiologic variables. There are wide individual differences in the magnitude of physiological responses shown during such a task, with some people (so-called "hot reactors") showing sizable increases to the challenging task, and others showing little or no increases. For example, there is some evidence that behaviors evidenced by hostile type A persons are accompanied by the same kinds of cardiovascular and neuroendocrine responses thought to link psychosocial stress to CHD (Contrada & Krantz, 1988; Krantz & Durel, 1983; Matthews, 1982).

Research has examined the possibility that excessive reactivity to stress may itself be a risk factor for coronary disease. In one study of initially healthy men followed for 23 years (Keys et al., 1971), the magnitude of their diastolic blood pressure reactions to a cold pressor test (which involves immersing the hand in cold water) predicted later heart disease. In fact, this physiologic response was a stronger predictor than many of the standard risk factors assessed in the study. However, a later study (Coresh, Klag, Mead, Liang, & Whelton, 1992) failed to replicate these findings.

Additional evidence of a relationship between cardiovascular reactions to stress and coronary disease was obtained in the Bowman–Gray monkeys described earlier. In studies of male and female cynomolgus monkeys fed on cholesterol-rich diet, animals were exposed to a standard laboratory stress (threat of capture) that produced large heart-rate elevations (Manuck, Kaplan, & Clarkson, 1983; Manuck et al., 1986). Animals were categorized as either high or low heart-rate reactive monkeys. At the end of the study, high heart-rate reactors had nearly twice the amount of coronary atherosclerosis as did low heart-rate reactors. Because of these animal and human studies, several behavioral methods for reducing reactivity have been studied. Among the behavioral techniques used for this purpose are cognitive techniques, relaxation training, biofeedback, and aerobic exercise (Jacob & Chesney, 1986; Matthews et al., 1986).

8.08.2.4 Treatment of CHD

Although the field of cardiac rehabilitation is comparatively young, it has made considerable inroads in the clinical management of coronary patients. Standard rehabilitation programs involve a combination of drug treatment, exercise, and dietary interventions (Blumenthal & Emery, 1988). The current status of interventions in this field focusing on medical and/or exercise interventions, has been documented in several reviews (Blumenthal & Emery, 1988; Lau et al., 1992; Oldridge, Guyatt, Fischer, & Rimm, 1988). Recently, more treatment plans for CHD have included psychological interventions, such as group and individual cognitive therapy, relaxation therapy, and meditation techniques. Because behavioral treatments for CHD must be implemented in the context of current medical practice, a brief overview of the medical and surgical treatment options for coronary disease is presented before describing psychosocial interventions in this area.

8.08.2.4.1 Medical and surgical treatment options

Medical and surgical treatment options for cardiac patients range from minimally invasive medical and drug treatments to coronary bypass surgery. Among the many pharmacological agents that have been proven useful for the treatment of CHD patients are: anti-ischemic agents, such as beta-blockers and calcium channel drugs, which reduce the heart's demand for blood and help the heart function more efficiently with a limited supply; nitrates, which are useful in the treatment of ischemia and anginal pain; various lipid-lowering drugs that reduce harmful cholesterol levels; aspirin and other drugs that reduce the clotting tendency of blood platelets; and agents that lower blood pressure. Other procedures, such as percutaneous transluminal angiography (PTCA) and coronary artery bypass grafting (CABG) are also commonly used in treatment. (PTCA and CABG are together referred to as revascularization procedures, as they aim to restore blood flow in areas where flow was previously restricted.) During PTCA, atherosclerotic points in selected arteries are widened by means of a balloon-inflation procedure. CABG involves the surgical bypassing of blocked sections of coronary arteries with sections of a saphenous vein, usually from the leg, or with portions of an artery from another part of the body. Studies indicate that CABG is effective in reducing anginal pain and improving functional status, but has only been shown to lengthen survival in specific subsets of CHD patients (Coronary Artery Surgery Study [CASS] Principal Investigators, 1984).

8.08.2.4.2 Exercise and behavioral components of cardiac rehabilitation

There are numerous behavioral components of successful comprehensive cardiac rehabilitation programs (e.g., Blumenthal & Emery, 1988; Krantz & Blumenthal, 1987). These include an aerobic exercise conditioning program, smoking cessation, weight loss, and maintenance of optimal weight, and modification of diet to emphasize foods low in saturated fat and cholesterol. Each of these interventions often involve significant and demanding behavioral changes, and issues of promoting behavioral change, ensuring compliance, and long-term maintenance of behavioral modifications are important in ensuring therapeutic effectiveness.

Exercise training is a core element of contemporary cardiac rehabilitation programs (for reviews see Blumenthal & Emery, 1988; Blumenthal & Wei, 1993). Physical inactivity is a significant and independent risk factor for CHD, and regular physical activity in the form of aerobic-type exercises increases functional capacity and plays an important role in both primary and secondary prevention. Active individuals have better cardiovascular risk factor profiles relative to their sedentary counterparts, including lower blood pressure, higher HDL cholesterol, lower LDL cholesterol, lower triglycerides, and very low density lipoprotein cholesterol levels. Physically fit individuals, in comparison to unfit persons, also have attenuated hemodynamic and neuroendocrine responses to behavioral stressors (Blumenthal & Wei, 1993).

Exercise improves functional capacity in most cardiac patients, including patients with limited exercise tolerance, and those who engage in regular physical activity may be better able to perform activities of daily living and enjoy many aspects of life. However, despite these positive effects, the precise effects of exercise training in prolonging life or reducing recurrence rates in post-MI patients is still the subject of some debate. Recent meta-analyses of controlled studies in rehabilitation have demonstrated significant reductions in mortality for patients assigned to rehabilitation in comparison with those assigned to control groups (Fletcher, 1996; Pate et al., 1995). However, these results have been difficult to demonstrate in individual studies, perhaps because large sample sizes are needed to reveal these effects.

Interventions to increase participation in physical activity generally indicate that, as with many lifestyle interventions, incentives and social support can increase exercise patterns in the short term, but that people have difficulty maintaining their exercise programs over the course of time (Blumenthal & Emery, 1988; Dubbert, 1995). Exercise maintenance is improved by integrating physical activity and exercise into everyday lifestyle. Because recent evidence suggests that stress management and psychosocial treatments have important beneficial effects on morbidity and on quality of life when implemented in conjunction with standard medical interventions, these interventions are reviewed in some detail in the following section.

8.08.2.5 Psychosocial Treatment Approaches for the Cardiac Patient

As noted previously, evidence suggests that psychosocial interventions may reduce morbidity and mortality, psychological distress, and some biological risk factors when used in addition to standard treatment regimens among cardiac patients. More specifically, Linden, Stossel and Maurice (1996) recently performed a meta-analysis of 23 controlled trials that evaluated the impact of psychosocial treatments directed specifically at reducing distress-related factors among cardiac patients. Results of this analysis indicated that patients receiving psychosocial treatments (e.g., stress management, individual or group cognitive therapy, and meditation) showed greater reductions, compared with control conditions, not only in psychological distress but also in blood pressure, heart rate, and serum cholesterol levels. Morbidity and mortality data, available in about half of these studies, indicated that patients not receiving psychosocial treatments showed greater mortality and cardiac recurrence rates during the first two years of follow-up (Table 1).

8.08.2.5.1 Modifying hostility and type A behavior

A variety of clinical intervention studies have attempted to decrease type A behavior either in persons with elevated levels of other CHD risk factors or in samples of coronary patients. Most of these early studies have demonstrated that elements of type A behavior can be decreased to some extent in subjects who are motivated to change (Allan & Scheidt, 1996; Suinn, 1982). Accompanying changes in type A behavior, some studies also measured changes in traditional CHD risk factors such as serum cholesterol levels or blood pressure. The findings from these studies are inconsistent (Allan & Scheidt, 1996; Suinn, 1982). These results are not surprising considering that the therapeutic regimens are not typically directed at decreasing risk factor levels other than type A behavior.

The most important and ambitious type A behavior intervention study done to date is the Recurrent Coronary Prevention Project (RCPP; Friedman et al., 1986). The major purpose of this project was to determine whether the constellation of type A behaviors—focusing on anger, impatience, aggressiveness, and irritability—could be modified in a large group of heart attack patients, and whether such behavior changes would lower the recurrence of heart attacks and deaths from CHD. Beginning in 1979, over 1000 patients were recruited for a five-year intervention study.

Patients were assigned to one of three groups: a cardiology counseling treatment group, a combined cardiology counseling and type A behavior modification group, or a no-treatment control group. The cardiology counseling included encouragement to comply with dietary, exercise, and drug regimens prescribed by the participants' personal physicians, education about CHD and its treatment, and counseling about psychological problems (other than type A behaviors) associated with the postcoronary experience. Type A behavior counseling included drills to change specific type A behaviors, focused discussions on beliefs and values underlying type A behavior, rearrangements of home and work demands, and relaxation training to decrease physiologic arousal.

In the final results of the study after 4.5 years, the rate of heart attack recurrence for the type A behavioral counseling group was significantly lower than for the cardiology counseling and control groups (Friedman et al., 1986). These results demonstrated, within a controlled experimental design, that an intervention directed at altering type A behavior reduces coronary disease recurrence in post-heart-attack patients. However, in light of the recent negative evidence regarding associations of type A behavior with CHD, it is possible that the beneficial effects of the RCPP study resulted from more general salutary effects of the interventions in reducing distress and increasing social support among patients.

8.08.2.5.2 Interventions to increase social support and reduce life stress

Another, perhaps more cost-effective, approach to preventing stress-related morbidity and mortality in cardiac patients was utilized by the Ischemic Heart Disease Life Stress Monitoring Program (Frasure-Smith & Prince, 1987,

Table 1 Benefit of psychosocial interventions for reductions in mortality and morbidity.

End-point	*No. of studies*	*No. of patients (control/experimental group)*	*Weighted log OR**	χ^2	*P*	*95% CI**

* Fully randomized, controlled trials only

1989), conducted in Montreal, Canada. This study made clinical use of the evidence that periods of increased life stress may precede recurrences of heart attack. Patients who had experienced a heart attack (or MI) were assigned to either a treatment group ($n = 229$) or to a control group ($n = 224$). Patients assigned to the control group did not receive life stress monitoring and intervention, but instead received routine medical follow-up care. In the treatment group, patients were contacted by phone on a monthly basis and asked about 20 symptoms of distress, such as insomnia, feelings of depression, and inability to concentrate. When stress levels exceeded a critical level (more than 4 of 20 possible symptoms), a project nurse made a home visit to assess the causes of increased distress, and attempted to help the patient with whatever life problems seemed to be producing the distress. Over the year of the program, about half of patients in the treatment group had high stress levels requiring intervention. On average, study nurses provided each high-stress patient with 5–6 hours of home nursing contact, including teaching patients about coronary disease, counseling, providing social and emotional support, and referring patients to cardiologists or other health professionals as needed.

The study hypothesized that by reducing stress the program would result in a reduction in cardiac mortality and in cardiac recurrences. Results showed that for the year of the project cardiac deaths were reduced by 50%, and that the reduced death rate persisted for six months beyond the end of the program (Figure 6). In addition, although there were similar rates of MI recurrences in the two groups, during the seven years following the program there were fewer MI recurrences among patients in the treatment group.

The most obvious explanation for the outcomes obtained in the Ischemic Heart Disease Life Stress Monitoring Program is that the program provided patients with a sense of social and emotional support that helped ameliorate depression and feelings of helplessness and distress, thereby reducing physiological arousal and its adverse effects on the cardiovascular system. The special clinical features of the program, including selection for treatment based on stress scores and individualized tailoring of interventions to patients" needs, may have been responsible for the program's success.

8.08.2.5.3 The lifestyle heart trial

One of the most important intervention studies conducted to date is the one carried out by Ornish and colleagues (Ornish et al., 1990). These researchers conducted a controlled study of 28 patients with significant coronary artery disease documented by coronary angiography (a procedure used to assess the severity of blockages in coronary arteries). Patients were randomly assigned to either an experimental group or to a usual care control group. Experimental group patients were given a lifestyle-modification program consisting of several components: (i) a very low fat vegetarian diet; (ii) stress management training and group support consisting of twice weekly yoga and meditation conducted in group sessions together with individual practice for one hour a day; (iii) a smoking cessation program; and (iv) a program of moderate levels of aerobic exercise. Patients assigned to the control group were not asked to make lifestyle changes other than those recommended in traditional cardiologic care. The intervention lasted for one year, and the extent of progression of coronary disease was assessed in all patients by comparing coronary angiograms obtained at the study onset and at one year.

The study results (Ornish et al., 1990) demonstrated that, for the experimental group, on average there was a slight reduction (regression) in the extent of stenosis (or blockage) in coronary arteries, whereas the controls showed a progression in severity of stenosis. Overall, 82% of patients in the experimental group had an average change toward regression of disease. Interestingly, the degree of measured regression of disease was related to the overall extent of adherence to the intervention recommendations among the study subjects, with the most compliant subjects showing the most improvement in disease status and the least compliant patients showing the least change (Figure 7).

Blumenthal et al. (1997) recently assessed the independent effects of stress management and exercise training on the prognosis of 107 cardiac patients with CHD and evidence of myocardial ischemia. In the Myocardial Ischemia Intervention Trial, patients were randomly assigned to a four-month program of stress management or exercise training. An additional control group of patients (those patients who lived too far from the intervention center to participate in the intensive and frequent treatment sessions) constituted a nonrandom usual-care group. To assess possible mechanisms associated with the effects of interventions, patients underwent mental stress and exercise testing for ischemia prior to and after the interventions. The results of the study indicated that, compared to controls, patients in the stress management group showed a lower risk of cardiac events over a

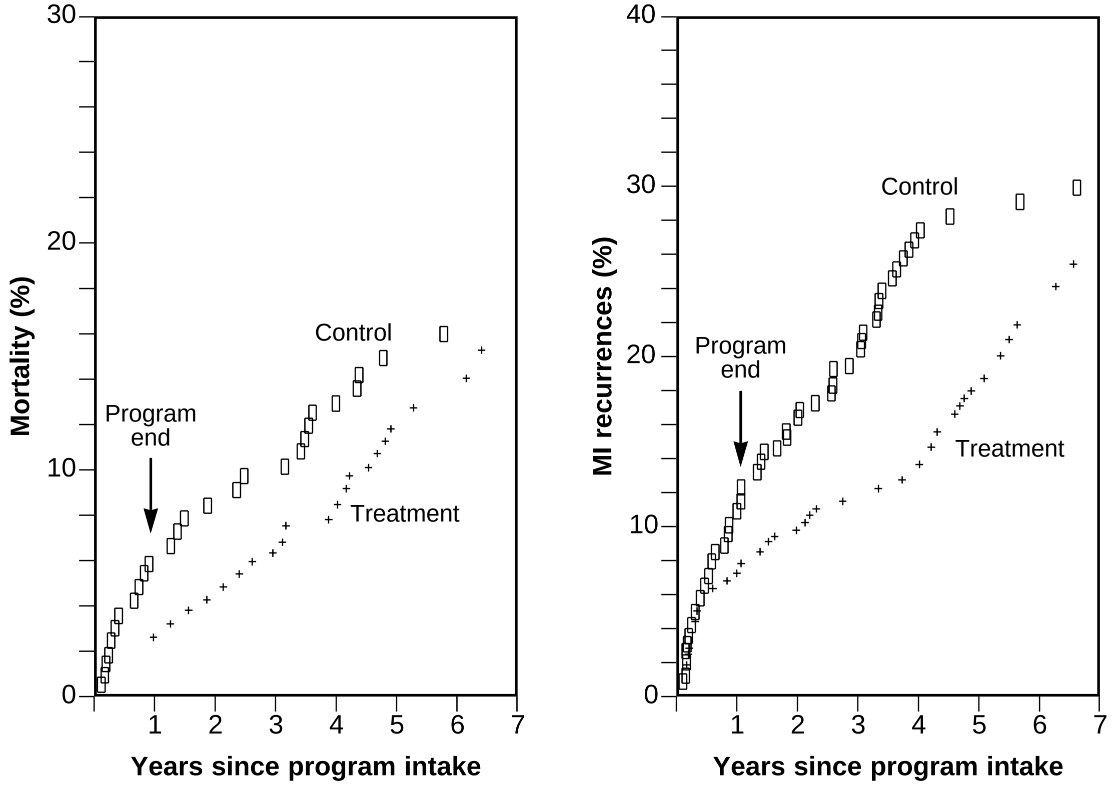

Figure 6 Long-term outcomes in the Ischemic Heart Disease Stress Monitoring Program.

mean follow-up period of 38 months. The risk of cardiac events in the exercise training group was lower than that of controls, but the effect did not reach statistically significant levels. Other beneficial effects of the stress management intervention included reduced occurrence of myocardial ischemia, lowered serum cholesterol levels, and reduced self-reported distress. One shortcoming of this study, however, was the failure to randomize patients to the usual-care control group. However, analyses failed to uncover any medical, demographic, or socioeconomic differences between control and treatment groups that could have accounted for the results obtained.

8.08.2.5.4 Summary

In summary, the identification of psychosocial risk factors for coronary disease has led to several promising behavioral and psychosocial interventions to aid in the treatment and prevention of coronary disease in high-risk individuals. Four such behavioral and psychosocial interventions with coronary patients were described: cognitive-behavioral interventions directed at lessening hostility and type A behavior (RCPP); a tailored social support and counseling intervention delivered by a nurse directed at reducing life stress (Ischemic Heart Disease Life Stress Monitoring Program); a lifestyle-modification program consisting of a very low fat vegetarian diet, a stress management training with group support and practiced individually, stopping smoking, and moderate levels of aerobic exercise (Lifestyle Heart Trial); and a controlled study of the effects of stress management interventions on cardiac ischemia and cardiac morbidity (Myocardial Ischemia Intervention Trial). As noted by Linden et al. (1996), the aggregate data provide a basis for the inclusion of psychosocial treatment components in cardiac rehabilitation. However, given the diversity of treatment approaches employed, these findings also suggest an important need to identify the most specific, most effective types of psychosocial interventions for particular patients.

8.08.3 ESSENTIAL HYPERTENSION

The term "essential hypertension" refers to an asymptomatic condition in which the blood pressure is chronically elevated, and for which no single cause can be identified. According to current diagnostic standards (Joint National

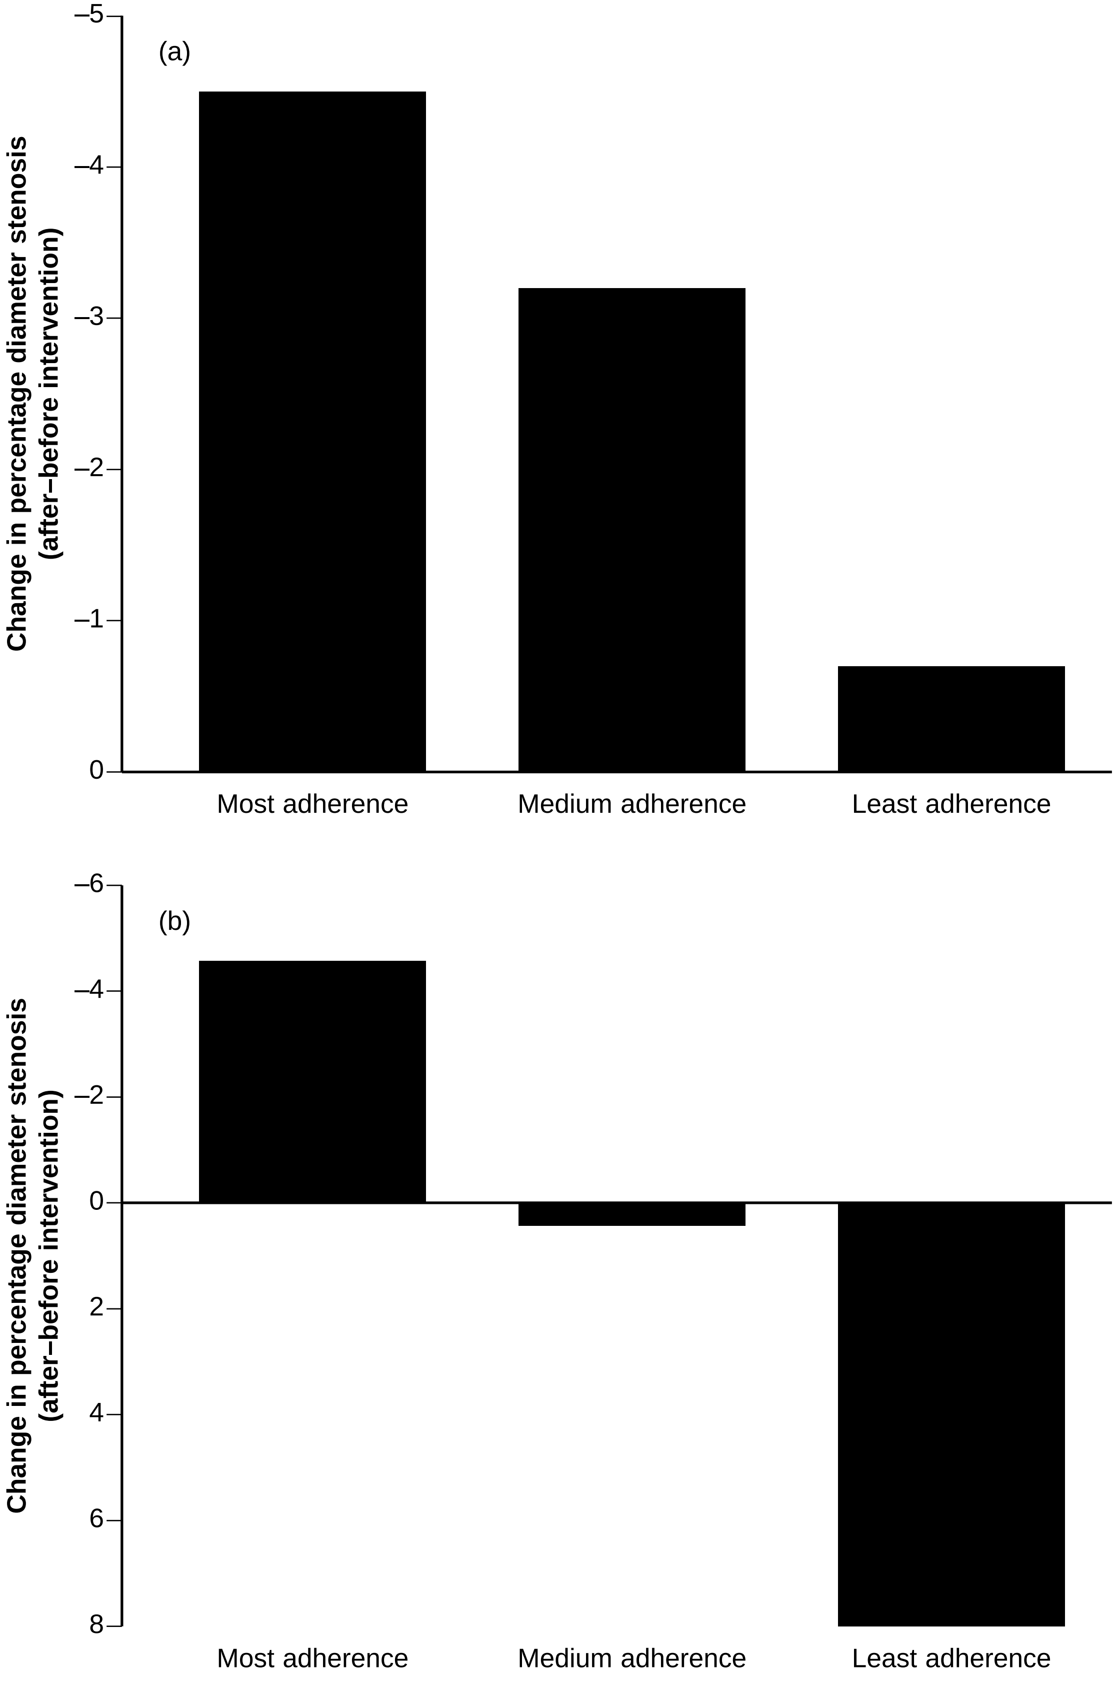

Figure 7 Disease regression measured in the study by Ornish et al. (1990): (a) experimental study group; (b) whole study group.

Committee on Detection, Evaluation, and Treatment of High Blood Pressure [JNC], 1993), hypertension is defined as a diastolic blood pressure consistently at or above 90 mmHg and/or a systolic blood pressure at or above 140 mmHg. Recent data further identify the optimal blood pressure as at or below 120/85 mmHg. The prevalence of essential hypertension in Western societies is high; for example, this condition is estimated to be present in 15% of the US population. Hypertension is a serious and potentially lethal disease, and untreated hypertension increases the risk of stroke, heart attack, kidney, and vascular disease. Progress in the control of hypertension over the past 30 years has been enormous, and although it is a chronic disease its control is now possible through a variety of pharmacologic as well as nonpharmacologic behavioral means.

Factors associated with risk of hypertension, include age, family history of hypertension, "borderline" high blood pressure, dietary intake of salt, and obesity. Like CHD, there are numerous social, environmental, and cultural factors that interact with genetic background in predisposing individuals to hypertension, and considerable attention has been paid to studying the role of stress and personality factors in the development of this disorder. In addition, there has been considerable attention devoted to cognitive and behavioral treatment approaches for essential hypertension, and these approaches have met with mixed results at best. It is likely that many findings in the area of the role of behavior in the development and treatment of hypertension are contradictory because of the complex interactions between behavioral, physiological, and genetic factors, and also because essential hypertension is probably not a single homogeneous disease. Rather, blood pressure is thought to progress over a period of years from moderately elevated or "borderline" levels to more appreciably elevated levels, the latter being called "established hypertension." The phenomenon of "white coat hypertension" has also been identified, in which individuals display elevated blood pressure when clinically examined in the doctors" office, but may display normal blood pressure when assessed in the patient's usual environment outside of the clinic (Pickering, James & Boddie, 1988; Siegel, Blomenthal, & Divine, 1990). It it likely that white coat hypertension results in an increase in "false-positive" diagnosis and treatment of high blood pressure, and the clinical significance of white coat hypertension remains a topic of current study (Dubbert, 1995).

Several different pathogenic mechanisms can bring about blood pressure elevations, and different physiologic and/or behavioral mechanisms are implicated at different stages of the disorder. For example, individuals with borderline and earlier stages of hypertension are commonly observed to have an elevated output of blood from the heart but little evidence of increased resistance to the flow of blood in the body's vasculature (Julius & Esler, 1975). This physiological pattern is consistent with an increased activation of the sympathetic nervous system, which is the body's initial reaction to psychological stress. Indeed, high levels of blood and tissue catecholamines (such as those produced by stress) have been found in some hypertensive humans and animals (Julius & Bassett, 1987; Julius & Esler, 1975). However, in older individuals with more established hypertension, the heart's output of blood is normal or even decreased and resistance to flow of blood is elevated.

8.08.3.1 Genetic–Environment Interactions

Evidence from animal research and from studies of human twins indicates that genetic factors are important in the development of hypertension (Pickering & Sleight, 1977). In humans, however, it is likely that sustained hypertension is produced by an interaction of environmental and genetic factors. Population studies reveal a difference in the prevalence of hypertension among various social and cultural groups, a difference that cannot be accounted for by genetic factors alone (Henry & Cassel, 1969). For example, even though African-Americans in the USA experience more hypertension than other groups, the prevalence of this disease is higher among poor than middle class black Americans (Harburg et al., 1973). Animal research similarly reveals examples where environmental factors, such as dietary salt intake or stress, can lead to sustained blood pressure elevations, but only in certain genetic strains (Dahl, Heine, & Tassinari, 1962).

8.08.3.2 Stress, Behavioral Factors, and Essential Hypertension

Sociocultural and psychological studies of humans, in conjunction with research on animals, have identified some factors related to behavior that might play a role in the development of hypertension. The increased risk for hypertension among blacks compared to whites in the USA and among persons of lower socioeconomic compared to higher socioeconomic status has been attributed to a variety of factors, including differences in dietary patterns, exercise habits, or the social and physical characteristics of the environments (including racism) (Krieger & Sidney, 1996) in which these individuals live and work (Julius & Bassett, 1987). Some studies have suggested that exposure to environments (e.g., urban high crime settings) that require sustained vigilance as well as recurrent mobilization of coping resources to ward off harm may raise blood pressure (Guttman & Benson, 1971; Henry & Cassel, 1969), and it is well documented that poorer people are overrepresented in such environments. For example, the role of stress in hypertension is suggested by a study of residents of Detroit (Harburg et al., 1973). Four areas were categorized as "high stress" or "low stress" based on socioeconomic status, crime rate, population density, residential mobility, and marital breakup rates. Blood pressure levels were highest among black high stress males, while white areas and black low stress areas did not differ in blood pressure levels. A recent report suggesting that racism may be linked to higher blood pressure in blacks (Krieger and Sidney, 1996) also supports this hypothesis. However, the simple notion that cultural change and social stress are causally linked to hypertension has been criticized as not being consistent with the aggregate data available (Syme & Torfs, 1978).

Research has also shown that people engaged in highly stressful occupations, such as workers in busy airport control towers, have more than four times the prevalence of hypertension when stress is high than individuals of similar age in other professions (Cobb & Rose, 1973). Current studies of urban bus drivers in several places in the world suggest that they also have higher rates of hypertension than demographically comparable groups of employed persons. The high rates of hypertension observed in these occupational groups is consistent with the job demand/control hypothesis advanced to explain the relationship between occupational stress and CHD (Karasek et al., 1982). Specifically, as with CHD, hypertension may occur more frequently in jobs that are demanding but in which there is little opportunity or flexibility to deal with these demands.

Experimental studies with animals further demonstrate that social or behavioral stress can produce hypertension in predisposed individuals. Classic studies by J. P. Henry and associates (Henry & Stephens, 1977) have shown that psychosocial stimuli can cause hypertension in mice. Other studies demonstrate that hypertension can be induced in animals exposed to environmental stressors such as fear or shock and experimentally produced conflict (Campbell & Henry, 1983). However, unlike the human condition, blood pressure tends to normalize when the stress is removed unless the animals are genetically predisposed to hypertension. Consistent with the notion that genetic–environment interactions are important in the development of hypertension, studies have demonstrated that strains of animals that are susceptible to hypertension are also likely to show stress-induced blood pressure elevations (Friedman & Iwai, 1976).

In humans, excessive stress and salt consumption might also interact in producing blood pressure elevations. Haythornthwaite, Pratley, and Anderson (1992) studied medical students during examination periods (high stress) and during vacation periods (low stress). Half the students were randomly assigned to consume salt tablets (sodium chloride) tablets or placebo tablets (a usual salt intake condition) during a two-week period of high or low stress. Results of the study indicated that high sodium intake during the high stress period was associated with greater elevations in resting systolic and mean arterial pressure than either the usual salt intake during the high stress period or the high salt intake during the low stress period. These results suggest that some forms of hypertension or blood pressure elevations may result from the interaction of psychosocial stress with periods of high salt intake.

8.08.3.2.1 Personality and essential hypertension

Beginning with the observation of early clinicians that patients with chronic hypertension showed certain personality features (e.g., Aymann, 1933), there has been a long-standing interest in personality correlates of essential hypertension (for reviews see Cottier, Perini, & Rauchfleisch, 1987; Johnson, Gentry, & Julius, 1992). Over time, several diverse personality characteristics have been identified or studied as being prevalent in hypertensives, with psychodynamic formulations driving early research in this area. Traits associated with hypertension in empirical studies have included, but are not limited to, suppressed hostility or anger (Dunbar, 1943; Harburg et al., 1973; Johnson et al., 1992), neuroticism and anxiety (Markovitz, Matthews, Kannel, Cobb, & D'Agonstino, 1993), and submissiveness (Elser et al., 1977). Although associations between these traits and hypertension have been widely reported, many existing studies suffer from methodological shortcomings, such as the use of selected or convenience samples, or the failure to distinguish in hypertensive patients characteristics (e.g., neuroticism) that may be prevalent in other diagnosed medical groups with chronic diseases. In addition, inconsistencies reported across studies in associations of certain traits with hypertension may have resulted not only from the aforementioned patient selection factors, but also from the fact that essential hypertension may not be a heterogeneous disease, progressing over a period of years from moderately elevated or "borderline" levels to more appreciably elevated levels (Weiner & Sapira, 1987).

Given the existence of a core of traits associated with blood pressure elevation, various investigators differ in their assumptions regarding the significance of personality trait differences in hypertension. Early psychosomatic investigators (e.g., Alexander, 1939; Dunbar, 1943) and more recent researchers (e.g., Jern, 1987) have postulated a causal role for personality traits in the development of hypertension. Other investigators (e.g., Esler et al., 1977; Weder & Julius, 1987) have suggested that personality traits associated with hypertension reflect excessive central and sympathetic nervous system arousal that may predispose to hypertension. Another perspective on personality traits in hypertensives has suggested that behavioral differences between hypertensive and normotensive populations that are reflected on personality tests result from the medical attention and labeling associated with the diagnosis of disease. For example, Irvine, Garner, Olmsted, and Logan (1989) noted that hypertensives who were aware of their diagnosis scored significantly higher than normotensives and than hypertensives unaware of their blood pressure elevation on neuroticism, trait and state anxiety, and self-reported type A behavior. However, an explanation in terms of labeling cannot account for the prospective association recently reported between anxiety in apparently normal individuals and the subsequent development of hypertension (Markovitz et al., 1993).

8.08.3.2.2 Salt intake

Salt intake is implicated as a factor causing or worsening essential hypertension, largely because excessive intake of sodium causes the kidneys to increase the volume of blood. However, studies indicate that high salt intake may only be related to high blood pressure levels in some cultures and population groups. For example, among people who live in underdeveloped tribal societies, sodium intake is often low, as is the prevalence of hypertension (Page, Danion, & Moellering, 1970). As individuals move or become acculturated to modern societies the prevalence of hypertension increases. This phenomenon has been discussed in terms of increasing stress with acculturation, but it has also been argued that acculturation is associated with increased salt intake and plays an equally important role in the development of hypertension (Page et al., 1970). Clearly, both the salt and stress explanations for the increased prevalence of hypertension in modern societies have some merit, and the research mentioned here suggests that salt consumption and exposure to stress might interact together to produce blood pressure elevations (Friedman & Iwai, 1976; Haythornthwaite et al., 1992).

8.08.3.2.3 Obesity

Obesity is another behavioral phenomenon that plays an important role in hypertension. There is an increased prevalence of hypertension in obese persons, although the precise reasons for this remain to be determined (Shapiro, 1983). Some have thought that it is merely that obese patients consume more sodium, but recent studies have demonstrated that weight loss without salt restriction can result in significant decreases in blood pressure (Reisen et al., 1978). For this reason, weight loss is an important behavioral method for managing high blood pressure.

8.08.3.3 Treatment of Essential Hypertension

Pharmacologic treatment by an increasingly broad variety of agents has revolutionized the treatment and control of hypertension. A landmark study in this area was the Hypertension Detection and Follow-up Program (HDFP, 1979). The HDFP, which is considered to have been a major breakthrough of modern medical care, studied a sample of 10 000 hypertensives. Half the patients were assigned to a special care group, involving a strict medication protocol, with the goal of normalizing blood pressure delivered via special community based clinics. A usual care group was returned to their usual sources of care available in the mid-1970s (the time of the study). Results indicated a significant decrease in overall mortality in the special care group. The beneficial effects of pharmacologic treatment were most evident in older patients and in black patients in the sample. This study convincingly demonstrated the benefits and efficacy of pharmacologic treatment of hypertension.

Because hypertension is a chronic, asymptomatic disease, to mitigate the life-long need to take medication, which often has side effects, a variety of nonpharmacologic behavioral interventions, including lifestyle interventions such as dietary modification, weight loss, exercise, and stress management, have been assessed as possible treatment approaches for essential hypertension. In this regard, a comprehensive set of behavioral changes, including weight loss, reduced salt intake, and exercise, are initial recommendations in the treatment of hypertension. If these approaches are not effective in normalizing blood pressure, medication is prescribed (JNC, 1993), and the aforementioned behavioral changes can lessen the amount of medication needed. In the following sections, we review the behavioral and lifestyle interventions used in the treatment of hypertension.

8.08.3.3.1 Weight loss and dietary salt restriction in hypertension management

Reduction of salt intake and weight loss have become important components of the nonpharmacological treatment of hypertension. Clinical trials completed in the last 10–15 years have shown that even relatively modest weight loss can have clinically significant effects on blood pressure over long periods, of up to 3–5 years in some studies (for a comprehensive recent review of the effects of dietary modification and weight loss interventions in hypertension see Dubbert, 1995). Dietary studies also indicate that decreasing sodium intake in the diet of hypertensives appears to have the salutary effect of lowering blood pressure, although these effects tend to be smaller than those obtained via weight loss (Dubbert, 1995). In accordance with the above discussion of genetic–environment interactions, we should note that high salt intake is correlated with increased prevalence of hypertension only in certain populations or groups, and that animal studies reveal that excessive salt intake results in sustained hypertension only in certain genetic strains (Dahl et al., 1962). Thus, we might expect salt restriction to be effective in lowering blood pressure only in certain susceptible individuals.

8.08.3.3.2 Effects of exercise training in hypertension

Dubbert (1995) has also reviewed the effects of exercise in the management of hypertension. Although several intervention studies have noted a beneficial effect of aerobic exercise training in hypertensives, the beneficial effects of exercise *per se* appear to be equivocal. Both positive and negative clinical trials of exercise have been reported in the literature (Kelley & McClellan, 1994; Martin, Dubbert, & Cushman, 1990) and, although meta-analyses (Kelley & McClellan, 1994) suggest significant beneficial effects of exercise training in hypertension, it is not clear to what extent these effects are due to the effects of weight loss. Thus, the role of exercise in the management of hypertension, independent of the effects of weight loss, remains an area of active research.

8.08.3.3.3 Effects of reducing alcohol intake

Evidence also suggests that a reduction in alcohol consumption is a behavioral change that can also have beneficial effects in the management of essential hypertension (Dubbert, 1995; MacMahon, 1987). In fact, because heavy drinking can both raise blood pressure and interfere with the efficacy of drug treatments for hypertension, the taking of a detailed drinking history and limiting daily alcohol intake to no more than two drinks per day has become standard recommended practice in hypertension treatment (JNC, 1993). The potentially beneficial long-term effects of reducing alcohol consumption among hypertensives who are heavy drinkers is currently being studied in a multicenter study in the USA (Cushman et al., 1994).

8.08.3.3.4 Effects of stress management, biofeedback, and other cognitive interventions in hypertension

Fostered by enthusiasm for exploring applications of biofeedback and stress management in medical conditions that occurred with the formation of the field of behavioral medicine, early studies suggested that techniques such as biofeedback and relaxation training could be used to modify the stress-induced components of high blood pressure, and thereby reduce blood pressure in hypertensive patients. Several studies have demonstrated that small but significant decreases in blood pressure (e.g., 15 mmHg systolic and 10 mmHg diastolic blood pressure) can be achieved in hypertensives after a series of training sessions with biofeedback or relaxation methods such as meditation, progressive relaxation, or yoga (for reviews see Dubbert, 1995; Eisenberg et al., 1993; Johnston et al., 1993). For example, one study that yielded positive effects was conducted by Patel and colleagues (Patel, Marmot, & Terry, 1981; Patel et al., 1985), who assessed the effects of eight weekly group sessions of training in breathing exercises, deep muscle relaxation, meditation, and a stress management program. Subjects were also instructed to practice relaxation, and meditation for 15–20 minutes at home daily and to try to relax during stressful daily activities. Compared with a control group, patients who received relaxation training showed decreases in both systolic and diastolic blood pressure over a follow-up period of up to four years after treatment. The magnitude of these changes were in the range of 7 mmHg in systolic and diastolic blood pressure. Early comparative studies of these various behavioral techniques indicated that no one of them is clearly superior to the others, with each producing modest declines in blood pressure (Shapiro et al., 1977). These reductions in blood pressure are achieved without any side effects or medical contraindications, thus enhancing the attractiveness and appeal of stress-reducing techniques as nonpharmacologic adjuncts to the treatment of hypertension.

Unfortunately, the results of more recent research and meta-analyses of an extensive body of controlled studies tend to reveal that most of the effects of stress management on hypertension appear to be relatively small and may be attributable to a mixture of nonspecific (i.e., placebo) effects and to habituation to repeated blood pressure measurements over the course of clinical trials (Dubbert, 1995; Eisenberg et al., 1993; Jacob, Chesney, Williams, & Ding 1991; Johnston et al., 1993). For example, Johnston et al. (1993) conducted a meticulously well-controlled study of the effects of stress management on resting and ambulatory blood pressure and on left ventricular mass (a measure of cardiac size that is a clinically important consequence of hypertension). Ninety-six mild hypertensives were studied, and underwent an extensive baseline evaluation to habituate them to the effects of blood pressure measurement. Subsequently, they were assigned to either 10 clinical sessions and practice at home of either stress management and relaxation training, or to a nonaerobic stretching condition control. Results indicated that patients' blood pressure fell during the habituation period, but neither resting nor ambulatory blood pressures were changed during the treatments. However, the magnitude of blood pressure increases produced by a stressful interview was reduced by stress managment. Thus, stress management appears not to be effective in lowering resting blood pressure among patients who are habituated to the measurement procedures. An interesting aspect of the study is that responses to acute stressors might be diminished by stress management. These general findings are corroborated by other recent studies of stress management conducted by Chesney, Black, Swan, & Ward (1987) at patients' worksites.

The only strong recent counterevidence for the efficacy of stress-management-like interventions comes from a recent set of studies by Schneider et al. (1995) and Alexander et al. (1996). These investigators report benefits of transcendental meditation on blood pressure in elderly African-American hypertensives. The discrepancies between these results and those of other recent trials may be due to the fact that blood pressure elevations among inner city blacks is stress related and therefore susceptible to stress reduction procedures. Alternatively, transcendental meditation may have unique effects not evident in other interventions, although prior analyses (e.g., Eisenberg et al., 1993; Jacob et al., 1991) appear not to corroborate this latter notion.

8.08.3.4 Adherence to Antihypertensive Treatments

As hypertension is a chronic, asymptomatic disorder, and because patients need to take medication that often has significant side effects (e.g., impotence, depression, and fatigue), nonadherence with antihypertensive medication regimens is a serious and prevalent problem. Descriptive studies indicate that fewer than 33–66% of patients comply with antihypertensive treatment regimens (Dunbar-Jacob, Wyer, & Dunning, 1991). Thus, the failure of patients to adhere to antihypertensive regimens is an important behavioral issue that has been investigated and clinically addressed by health psychologists. A comprehensive consideration of the problem of patient nonadherence to medical regimens used in the treatment of hypertension and other chronic diseases is beyond the scope of this chapter, and this issue will only be touched upon briefly here. For thorough considerations of this issue the reader is referred to Dunbar-Jacob et al. (1991) and Haynes, McKibbon, & Kanai (1996).

Research suggests that there are important differences between treatment settings in reported antihypertensive compliance rates, with family practice settings observing higher compliance and hospital clinics reporting poorer rates (Dunbar-Jacob et al., 1991). Interventions to increase adherence to regimens have demonstrated that factors such as increasing provider and family support, simplifying and making the regimen less complex, and introducing several behavioral self-management strategies may be effective in some situations. Nevertheless, the problem of antihypertensive compliance remains widespread.

Unfortunately, our inability to measure noncompliance precisely hinders interpretation of these data. The various ways in which compliance and noncompliance are assessed (e.g., patient self-report, physician report, and pill count) are not always accurate, and each one provides a separate set of problems. One of the more exciting developments in the area of compliance is the development of electronic pill monitors, which permit the unobtrusive and accurate assessment of medication compliance during daily life (Dunbar-Jacob, Sereika, Rohay, & Burke, in press).

8.08.3.5 Summary

In summary, behavioral influences on essential hypertension include excessive salt intake, obesity, and stress. There is evidence that inner city African Americans and those subject to racism are more prone to hypertension, and animal studies suggest that stress can result in hypertension in genetically susceptible strains. However, the effectiveness of behavioral intervention techniques, such as relaxation training, biofeedback, and meditation, in lowering blood pressure have been rather small and are generally of questionnable clinical significance. However, behavioral interventions such as weight loss, physical conditioning, and reduction of dietary salt intake have proven effective as adjuncts to pharmacologic interventions for hypertension. In addition, patient nonadherence to antihypertensive medication regimens is an important and prevalent problem that remains a topic of current study.

8.08.4 CONCLUSION

There are many environmental, behavioral, and physiological variables that interact in the development of cardiovascular disorders. Many of the standard CHD risk factors have important behavioral components, and increasing evidence suggests important psychosocial risk factors for CHD, including occupational stress, hostility, and physiologic reactivity to stress. In cardiac patients, the presence of acute stress, low social support, lack of economic resources, and psychological depression also appear to be important psychosocial risk factors. The identification of psychosocial risk factors for coronary disease have led to several promising behavioral and psychosocial interventions to aid in the treatment and prevention of coronary disease in high-risk individuals.

There also appear to be important biobehavioral influences in the development and treatment of essential hypertension. These include excessive salt intake, obesity, and stress. Evidence also indicates that genetic and environmental factors interact in the development of hypertension. However, the modest effects of behavioral stress-reducing techniques such as relaxation training, biofeedback, and meditation in lowering blood pressure have proven disappointing. Nevertheless, the important necessity for the involvement of health psychologists in the treatment of essential hypertension is underscored by the potential efficacy of weight loss, dietary modification, and exercise conditioning, as well as the need to ensure that patients adhere to medication regimens in order for pharmacologic interventions that have been shown to reduce subsequent morbidity to be effective.

8.09.1 INTRODUCTION

The cost of human lives to cancer (defined as any malignant tumor; Rothenberg, 1992), is overwhelming. In many countries cancer is the second leading cause of death, only outnumbered by heart disease. In the USA alone, over 3500 people are diagnosed with cancer and another 1500 people die from cancer-related deaths *per day* (Parker, Tong, Bolden, & Wingo, 1997). While much of the increase in cancer incidence and mortality over the years appears related to advances in early detection as well as the general aging of the population (age is a risk factor; Garfinkel, 1994), Cunningham (1997) has noted cancer death rates may now be showing a downward trend in the USA. There is, however, variability across countries. For example, age-adjusted death rates per 100 000 population across sites and gender for 1990–1993 ranged from 394 in Hungary to 139 in Albania; the rate for the USA is 276 (average: Parker et al., 1997). In short, cancer is a significant medical problem that affects the health status of millions of people worldwide.

Research on the psychological, social, and behavioral aspects of oncology began in the early 1950s; however, our knowledge base has significantly expanded since the 1970s. In particular, research has clarified relationships between psychological responses (e.g., personality, mood, coping style, relationships), social factors (e.g., presence/absence of partner, degree of social support), and behavioral variables (e.g., compliance with treatment, diet, exercise). More recent research has incorporated biologic systems (e.g., immune and endocrine), examining the interaction of psychological, social, and behavioral variables and their relationship to disease course (see

Fawzy et al., 1993, for an example; see Andersen, Kiecolt-Glaser, & Glaser, 1994, for a discussion).

This chapter includes an overview of the central findings on the psychological, social, and behavioral impact of cancer. By way of introduction, we begin by addressing the magnitude of the cancer problem. Data on cancer incidence, death rates, and gender differences are highlighted. Where data from the USA are used, it is noted that they represent the same general trends found in other industrialized, Western countries. Second, we briefly discuss etiologic and risk factors and the role of prevention. The largest section of the chapter organizes research findings by disease relevant time points, from symptom discovery to recovery or death. Where appropriate, specific intervention studies will be detailed. Information about cancer's impact on a patient's social network (spouse, family, etc.) is also included. We conclude with a discussion of psychological interventions and techniques that appear to be effective in promoting improved quality of life and coping in cancer patients.

8.09.2 MAGNITUDE OF THE PROBLEM INCIDENCE, DEATH RATES, AND GENDER DIFFERENCES

Cancers vary in their prevalence and mortality. Tables 1 and 2 display data from the USA on the incidence and death rates by specific sites and genders. These data indicate, for example, that the most common diagnosis for women is breast cancer and for men, prostate cancer, but that lung cancer is the number one killer for both (Parker et al., 1997). Similarly, Tables 3 and 4 provide death rate data from selected countries (Parker et al., 1997). These data illustrate the geographic, nationality, and sex differences that exist (e.g., lung cancer death rates of 81.6 per 100 000 for Hungarian men, but a rate of 5.2 for French women). In examining the death rates worldwide, the top killers of women include breast, colon and rectum, lung, and stomach cancers. For men, lung, stomach, colon and rectum, and prostate cancers are the common killers worldwide.

8.09.3 ETIOLOGY, RISK FACTORS, AND PREVENTION

The specific events that turn a normal cell into a cancerous cell are still unknown (Rugo, 1993). However, we do know that it takes generations of mutations for cells to become cancerous. The development of cancer within an individual appears to depend on genetic or environmental factors, with exposure to carcinogens often playing a significant role in many cancers (Rugo, 1993). In fact, cancer incidence and concomitant premature death have been linked to behavioral habits that increase exposure. In the United States, for example, the National Cancer Institute set a goal of a 50% reduction in cancer mortality by the year 2000 through prevention and control efforts focused, in large part, on lifestyle (Greenwald & Cullen, 1985).

Primary prevention tactics have attempted to reduce the probability of cancer onset by decreasing exposure to risk factors. For women and men, unhealthy habits have been a behavioral research target, and smoking has been emphasized, as it is related to 30% of all cancer deaths (Rugo, 1993). Cigarette smoking is directly linked to lung cancer, one of the leading causes of death for men and women, and is implicated in cancers of the larynx, head and neck, esophagus, bladder, kidney, pancreas, and stomach.

Other lifestyle behaviors that have been linked to greater risk are dietary patterns and sun exposure (e.g., ultraviolet light). Diet research has suggested that diets high in fat and low in fiber may contribute to increased risk for particular cancers (e.g., breast and colon, respectively). Recommendations for modification—reductions in fat intake and increases in complex carbohydrates and fiber—and weight reduction *per se* have been suggested (Ashley, 1993; Wynder & Cohen, 1993). In breast cancer prevention, for example, interventions have been developed for at-risk women to reduce weight and fat intake and to increase physical activity (Heber, Bagga, Ashley, & Elashloff, 1993). Parallel interventions focused on increasing fiber in the diet may be important for decreasing one's risk for gastrointestinal cancers. Concerning sun exposure, the number of people diagnosed with skin cancers has been steadily increasing over recent years. In fact, close to 1 million diagnoses of basal and squamous cell skin cancers are expected in 1997 and this figure does not include malignant melanoma (Parker et al., 1997). It has been recommended that time spent exposed to the sun, especially during the hottest part of the day, be decreased and the use of lotions that block exposure to harmful ultraviolet rays be used. Another risk factor involves exposure to certain viruses. The human papilloma virus has been linked to gynecologic cancers and the human immunodeficiency virus has been associated to non-Hodgkin's lymphoma and Kaposi's sarcoma. Prevention efforts have focused on safer sexual practices with barrier methods (e.g., diaphram,

Table 1 1997 estimates of cancer incidence by site and gender for the five leading sites.

Male (total estimated 785 800)		*Female (total estimated 506 000)*	
Site	*Number (%)*	*Site*	*Number (%)*
Prostate	334 500 (43)	Breast	180 200 (30)
Lung	98 300 (13)	Colon/rectum	79 800 (13)

use of condoms). Additionally, a family history of cancer may double a person's risk for that same cancer. For example, in breast cancer, the greater the number of affected relatives and the younger these relatives were at the time of diagnosis, the higher a woman's risk. Women with multiple first-degree relatives (e.g., mother, sisters) with premenopausal breast cancer are at highest risk. In such families, breast cancer appears to be transmitted as a gene, and the risk of breast cancer may approach 80%. New evidence is also emerging on a gene associated with the development of prostate cancer.

Secondary prevention efforts have been defined as those that identify the disease at the earliest of stages (e.g., when it is preinvasive or localized and asymptomatic) so that effective treatment can be administered sooner and mortality reduced. The chances of successful early cancer detection and treatment depend upon the clinical characteristics of the disease and the screening strategy, and it is unlikely that secondary prevention can proceed effectively unless certain conditions for both are met.

Behavioral scientists have focused mainly on the early detection of breast cancer, especially with mammography (the most reliable means of early detection). Investigators (e.g., Rimer, 1992) have considered the psychological, behavioral, sociodemographic, and healthcare factors that appear to be related to women's usage of mammography. Older women, poorer women, and those with weak linkages to the healthcare system, for example, are less frequent users of mammography. Factors such as these result in deadly consequences for women, as poorer or older women without a history of mammography are often diagnosed with more advanced disease. Thus, to the extent that behavioral scientists can affect women's acceptance and utilization of the technique, survival may be directly improved. Early detection efforts have also focused on prostate, skin, and colorectal cancers with behavioral scientists finally beginning to study prostate cancer.

8.09.4 PSYCHOLOGICAL, SOCIAL, AND BEHAVIORAL IMPACT OF CANCER

8.09.4.1 Symptom Appearance

In the study of delay in seeking treatment for medical conditions, several definitions of delay have been used, but an oft-chosen operationalization is the number of days from the detection of the first symptom to an end point. This latter variable is less consistently chosen, but has included seeing a physician for symptoms (e.g., Coates et al., 1992; Waters, Nichols, Wheeler, Fraser, & Hayes, 1983), being diagnosed with a medical condition (Marshall, Gregorio, & Walsh, 1982), or beginning treatment for the condition (e.g., Howson, 1950). According to this view, all individuals, and even some physicians, would be "delayers." Still another strategy has been to designate some delay as more "reasonable" than others (e.g., one month from symptom appearance to appearance before a physician; see early work in cancer by Pack & Gallo, 1938).

Andersen and Cacioppo (1995) have conceived of delay as comprising a series of stages (e.g., appraisal, illness, behavioral, scheduling) each governed by a conceptually distinct set of decisional and appraisal processes. Appraisal delay, delay surrounding symptom interpretation, has been found to account for most of the delay in seeking a cancer diagnosis (see Andersen & Cacioppo, 1995, for a model of delay). For example, the appraisal interval was approximately 80% of the total delay for women with gynecologic cancer, whereas for women with breast symptoms, a site that has a narrower range of symptom diversity, the interval accounted for 60% of the delay.

It is likely that there are several reasons for the finding of appraisal processes accounting for the bulk of the delay time. First, the development of malignancy and the appearance of cancer symptoms are protracted, and a complex and changing symptom picture can be typical, unlike the presentation of many other medical problems (e.g., myocardial infarction; see Matthews, Siegel, Kuller, Thompson, & Varat, 1983). Symptoms can also vary with the site and extent of the disease. For example, ovarian cancer has varied presentations—pelvic cramping, low back pain, pain or bleeding with intercourse, urinary frequency irregularities. Moreover, as cancers progress, they can involve other bodily systems (e.g., gastrointestinal, lymphatic) and the symptom picture tends to change from specific or localized complaints (e.g., vaginal discharge/bleeding) to diffuse ones (e.g., loss of appetite, nausea, flu symptoms). Finally, cancer is a life-threatening disease but a low probability disease for many, and thus the appraisal process may lengthen.

Briefly considering the other stages, illness delay is defined as the number of days elapsing from the time an individual concludes he or she is ill to the day he or she decides to seek medical help. At this time individuals must decide, for example, whether to seek assistance from others (e.g., physician, others with a similar condition) or to self-treat the illness. After this, the delay is spent in making two remaining decisions. One is the delay between the decision to seek medical attention and the person acting on this decision by making an appointment (behavioral delay). The other is the time that elapses between the person making an appointment and his or her first receipt of medical attention (scheduling delay). Economic factors such as affordability, social factors such as family influence, and cognitive factors such as the extent to which the decision to seek medical help is based on issue-relevant thinking are more likely to modulate the delay time between a decision to seek and an action to receive medical care (behavioral delay). In contrast, both patient characteristics (such as the manner in which the person describes his or her concerns and symptoms) and medical environment characteristics (such as a physician's appointment backlog), which are not under an individual's control, may modulate the delay incurred when scheduling an appointment. Therefore, shortening delay to seeking a diagnosis once symptom/sign awareness has occurred (tertiary prevention) would improve survival, as early detection is linked to improved survival rates for many sites (e.g., cervix, breast, colon, prostate).

8.09.4.2 Diagnosis

An early clinical study suggested that the diagnosis of cancer produces an "existential plight," meaning that the news brings shock, disbelief, and emotional turmoil (Weisman & Worden, 1976). Today, we know that individuals even become alarmed at the time of medical screening, long before a cancer diagnosis is suggested (Wardle & Pope, 1992). Perhaps because of these natural, difficult reactions, over the years there has been some variability in whether or not patients were told that their diagnosis was cancer.

In the USA as well as most Western countries, patients (including children) are now told that their diagnosis is cancer, since this is regarded as the moral, ethical, and legal procedure to follow (Woodard & Pamies, 1992). Support of this policy has documented the beneficial effects of coping successfully with an extreme stressor such as cancer (Taylor, 1983), and follow-up studies of childhood leukemia survivors, for example, have pointed toward more favorable long-term adjustment for children when they learn of their diagnosis early, whether directly, accidentally, or through their own efforts, in comparison with children who learn late (Slavin, O'Malley, Koocher, & Foster, 1982). Likewise, Mosconi, Meyerowitz, Liberati and Liberati (1991) found that of 1171 Italian breast cancer patients, those who were told their diagnosis was cancer were more satisfied with the information they had received from their physicians. Still other cross-cultural research has indicated that the majority of patients want to be told their diagnosis truthfully (e.g., Japan, Mizushima et al., 1990; UK, Sell et al., 1993). Further, the manner in which the information is disclosed is important. Physicians who communicate hope have patients who are more hopeful, more favorable towards their cancer diagnosis, and who report more favorable overall emotional adjustment (Sardell & Trierweiler, 1993). This points to the need of physicians and other health professionals to learn more effective and thorough means of communicating information (e.g., diagnosis, treatment, prognosis) to their patients (Sell et al., Woodard & Pamies, 1992).

Empirical reports clarify the specific emotions—sadness (depression), fear (anxiety), and anger—that characterize this period. It is not surprising that depression is the most common affective problem. Survey estimates for major depression are of the order of 5–6% (Derogatis et al., 1983; Lansky et al., 1985), similar to that of the general population (Locke & Regier, 1985). However, when major depression and depressed mood are considered, prevalence rates are higher (e.g., 16% in Derogatis et al., 1983; 25% in a review by Massie & Holland, 1990). Lower rates have been found when specified diagnostic criteria are used and/or the patients assessed are ambulatory with good physical functioning (Levin, Jones, & Sack, 1993; Massie & Holland, 1990). In general, depression is more common for those patients in active treatment rather than those on follow-up, receiving palliative rather than curative treatment, with pain or other disturbing symptoms rather than not, and/or with a history of affective disorder or alcoholism.

Study of the psychological responses that characterize the response to cancer diagnosis may shed light on the reactions of individuals to other life-threatening disease or treatment circumstances. In fact, when moods (Cassileth et al., 1985; Westbrook & Viney, 1982) or coping strategies (Felton, Revenson, & Hinrichsen, 1984) have been compared across disease groups (e.g., rheumatoid arthritis, diabetes, cancer, renal disease, hypertension), few differences have been found, suggesting that cancer patients may respond similarly to those with other life-threatening and/or chronic illnesses. On the other hand, patients in these early studies were heterogeneous on many disease variables (e.g., time since diagnosis, active treatment vs. follow-up status, and/or disability) that are important predictors of differential responses among cancer patients.

Differences in the patterns of emotional distress may exist. For example, it has been suggested that breast and gynecological cancer patients are significantly less depressed, anxious, and hostile (angry) possibly due to perceptions of their illness as less serious than women with other forms of cancer (e.g., lung, gastrointestinal, head and neck; Sneed, Edlund, & Dias, 1992). Similarly, a comparison of patients with limited vs. extensive lung cancer and equivalent levels of physical impairment found that significantly greater mood disturbance was reported by the patients with extensive disease and poorer prognoses (Cella et al., 1987). Related findings have emerged for individuals who perceive their illness as severe (Marks, Richardson, Graham, & Levine, 1986) or who have a sense of pessimism about their life (Carver et al., 1994). In fact, Carver et al. found that general pessimism (vs. optimism) at diagnosis predicted poorer well-being (mood and life satisfaction) at one day before surgery as well as at 3, 6, and 12 month follow-ups. In addition, when patients are followed longitudinally, the emotional responses at recurrence are characterized by significantly higher levels of depression and anger than had been reported at the time of initial diagnosis (Andersen, Anderson, & deProsse, 1989b).

It is encouraging that the clinical problem of diagnostic and treatment-related distress can be alleviated through psychological interventions (see Andersen, 1992, for a review). A comprehensive example of such an effort is the study of Fawzy, Cousins et al. (1990) and Fawzy, Kemeny et al. (1990). They attempted to reduce distress and enhance immune functioning in newly diagnosed melanoma patients via a structured group support intervention which included health education, illness-related problem solving, relaxation training, and group support. The format was weekly group treatment for six sessions. Eighty patients with early stage melanoma participated and were randomized to intervention or control conditions. The post-treatment analyses indicated that the intervention subjects reported significantly more vigor, but there were no other emotional distress differences. By six months, emotional distress had improved for the intervention subjects with significantly lower depression, confusion, and fatigue, and higher vigor. Coping data indicated that the intervention subjects reported significantly more use of active-behavioral strategies by the treatment's end, a pattern that continued with the addition of active-cognitive strategies by six months. Regarding the immunologic findings, at six months there was a significant difference in groups with better immunologic status for the intervention subjects. These data are impressive in that they suggest that improvements in psychological status and coping are associated with changes (upregulation) in immune responses.

Improvements such as these in mood and coping are all the more impressive because they are often achieved with brief, cost-effective interventions (e.g., 10 therapy hours with delivery in a group format; Andersen, 1992). Studies that have provided follow-up data also suggest some consolidation of intervention effects across time (upwards of six months post-treatment), with lowered emotional distress, enhanced coping, and/or improved sexual functioning (e.g., Capone, Good, Westie, & Jacobson, 1980; Christensen, 1983).

8.09.4.3 Treatment

A certain component of the emotional distress occurring at diagnosis is due to the anticipation of treatment. Current therapies include surgery, radiotherapy and radioactive substances, chemotherapy, hormonal therapy, immunotherapy, and combination regimens and procedures (e.g., bone marrow transplantation, intraoperative radiotherapy). Some patients also undergo difficult diagnostic or treatment monitoring procedures (e.g., bone marrow aspirations), and all treatments are preceded or followed by physical examinations, tumor surveys, and/or laboratory studies. Thus, the diagnostic process of selecting the appropriate therapy and subsequent treatment events can represent multiple medical stressors. As will be discussed below, the data are consistent in their portrayal of more distress (particularly fear and anxiety), slower rates of emotional recovery, and, perhaps, higher rates of other behavioral difficulties (e.g., food aversions, continued fatigue and malaise) in cancer patients compared with healthy individuals undergoing noncancer-related medical treatment. The emotional crisis that characterizes the diagnostic period lessens as time passes, and longitudinal studies find that as treatments end and recovery begins there is an emotional rebound (e.g., Andersen et al., 1989b; Bloom, 1987; Devlen, Maguire, Phillips, Crowther, & Chambers, 1987; Edgar, Rosberger, & Nowlis, 1992). This lowering of emotional distress over time is found even for patients undergoing radical treatment requiring major adjustments (e.g., radical neck dissection with laryngectomy; Manuel, Roth, Keefe, & Brantley, 1987). As cancer treatments (surgery, radiation, etc.) vary considerably in their intent, morbidity, and mortality, we will review each of the major modalities separately and also discuss three clinical problems—compliance, appetite and weight loss, and fatigue—that are common across therapies.

8.09.4.3.1 Surgery

There have been few investigations of cancer surgery, but there are numerous descriptive and intervention studies of the reactions of healthy individuals undergoing surgery for benign conditions. The latter studies are consistent in their portrayal of (i) high levels of self-reported preoperative anxiety predictive of higher postoperative anxiety, and (ii) higher postoperative anxiety predictive of longer recovery (e.g., decreased time out of bed, increased pain reports). What may distinguish cancer surgery patients are higher overall levels of distress and slower rates of emotional recovery. For example, Gottesman and Lewis (1982) found greater and more lasting feelings of crisis and helplessness among cancer patients in comparison to benign surgery patients for as long as two months following discharge.

Considering these data, findings on the interaction patterns of physicians and cancer patients on morning surgical rounds is disturbing. Blanchard, Ruckdeschel, Labrecque, Frisch, and Blanchard (1987) found attending physicians on a cancer unit less likely to be supportive and to address patients" needs than physicians treating general medical patients. The heavier volume and more seriously ill patients common to cancer units might be sources for this unfortunate relationship. Related findings indicate that oncology nurses might find their job significantly more stressful than other taxing assignments (e.g., cardiac, intensive care, or operating room; Stewart, Meyerowitz, Jackson, Yarkin, & Harvey, 1982), and may limit their communication with cancer patients, especially those experiencing a recurrence (Wilkinson, 1991).

As noted above, there has been considerable research on the psychological and behavioral aspects of response to surgery, and many effective interventions have been tested. Components of these interventions include procedural information (e.g., how the surgery is to be performed as well as pre- and postoperative events from the perspective of the patient), sensory information on the actual physical sensations of the surgery or preparatory events, behavioral coping instructions, cognitive coping interventions, relaxation, hypnosis, and emotion-focused interventions. In a meta-analysis of this literature, Johnston and Vogele (1993) reported that procedural information and behavioral instructions show consistent and strong positive effects on postoperative recovery. Effects are significant for a broad band of measures, including ratings of negative affect and pain, amount of pain medication, length of stay, behavioral recovery, and physiological indices.

8.09.4.3.2 Radiotherapy

At least 350 000 individuals in the USA receive radiation therapy each year. Clinical descriptions have noted patients" fears (e.g., being burned, hair loss, sterility); while such outcomes do occur, they are site- and dosage-dependent. To understand radiation fears, the surgical anxiety studies already described above have been used as a research paradigm. Here, again, anxiety (and sleeplessness) can often cause more overall distress than physical symptoms (Munro, Biruls, Griffin, Thomas, & Vallis, 1989), and are predictors of treatment response (Wallace, Priestman, Dunn, & Priestman, 1993). If interventions to reduce distress (especially anticipatory anxiety) are not conducted, heightened post-treatment anxiety is also found (Andersen, Karlsson, Anderson, & Tewfik, 1984; Andersen & Tewfik, 1985) and might be maintained for as long as three months post-therapy, particularly when treatment symptoms linger (e.g., diarrhea, fatigue; King, Nail, Kreamer, Strohl, & Johnson, 1985). When acute side effects resolve (usually by 12 months post-treatment), there appears to be no higher incidence of emotional difficulties for radiotherapy patients than for cancer surgery patients (Hughson, Cooper, McArdle, & Smith, 1987).

8.09.4.3.3 Chemotherapy

Of all the treatment modalities, the greatest progress has been in the understanding of psychological reactions to chemotherapy and the related toxicities, particularly nausea and vomiting. Over a decade of research has revealed that approximately 60% of cancer patients will develop nausea and another 50% will develop vomiting in response to cytotoxic treatments (Morrow & Hickok, 1993). Psychological research has focused on eliminating or reducing these problems through hypnosis (e.g., Redd, Andersen, & Minagawa, 1982), progressive muscle relaxation with guided imagery (e.g., Burish & Jenkins, 1992; Carey & Burish, 1988), systematic desensitization (e.g., Morrow et al., 1992), cognitive distraction (e.g., Greene, Seime, & Smith, 1991; Vasterling, Jenkins, Tope, & Burish, 1993), and biofeedback (e.g., Burish & Jenkins).

The routine use of antiemetic and antianxiety drugs and the development of newer chemotherapeutic agents has resulted in an overall lower incidence and clinical severity of nausea and vomiting. However, the above gains may be somewhat offset by the more current medical practice of using dose-intensive regimens as well as treating disease types or stages not previously given adjuvant chemotherapy (Andrykowski, 1993). It is clear that pretreatment with medications can control nausea and thus reduce vomiting, but pretreatment can also reduce the likelihood of anticipatory reactions. Anticipatory reactions are believed to be conditioned responses resulting from the learning process of classical conditioning in which side effects (e.g. nausea and vomiting) become associated with previously neutral stimuli (driving to the hospital, sitting in the waiting room, etc.). Once anticipatory nausea and vomiting develops, antiemetics are less effective, and it has been suggested that behavioral strategies should be used to aid patients (Andrykowski, 1993; Morrow & Hickok, 1993; Redd, 1993). Other research that may be helpful includes identifying the characteristics of individuals (e.g., high pretreatment anxiety or autonomic activity; severity of post-treatment vomiting in the early cycles; age; susceptibility to motion sickness or gastrointestinal distress), as well as characteristics of the agents (e.g., rated emetogenic potential of the regimen, dosages, rate of infusion) that place patients at risk of the development of nausea and vomiting (see Carey & Burish, 1988, or Morrow, 1986, for empirical tests of variables; see Morrow & Hickok, 1993, for a review of the potential variables).

8.09.4.3.4 Bone marrow transplantation

Over the past two decades, bone marrow transplantation (BMT) has evolved from an experimental procedure performed only when conventional therapies have failed (e.g., recurrent breast cancer) to an effective therapy considered as an alternative worthy of study in clinical trials as a first-line therapy (Baker, Curbow, & Wingard, 1991). It was initially used only for those with lymphohematopoietic malignancies or disorders characterized by bone marrow failure (e.g., leukemia, Hodgkin's disease, and non-Hodgkin's lymphoma; Wingard, Curbow, Baker, & Piantadosi, 1991), but is now being used with a variety of solid tumors (e.g., neuroblastomas, germ cell tumors, and cancers of the breast and ovary). The rapid acceptance and expanded use of this toxic modality is no less than dramatic. For example, a Phase II study has begun in the USA for BMT as an adjuvant treatment for breast cancer patients with 10 or more positive lymph nodes (Winer & Sutton, 1994). If beneficial, it is possible that thousands of breast cancer patients may undergo BMT as a standard treatment for metastatic as well as regional disease in the near future (Winer & Sutton, 1994). At present it is estimated that there are over 5000 transplants performed each year worldwide (Alby, 1991).

BMT is a complex and potentially fatal treatment. The target of the treatment, the bone marrow, is destroyed with high dose chemotherapy, with or without whole body radiation afterwards. The bone marrow to be transplanted comes from a donor (allogenic BMT) or from the patient (autologous BMT) after it has been removed and treated. Although allogenic BMT has a role, its expansion is limited by the need for a suitable donor and the subsequent risk of graft vs. host disease for the patient. In the case of autologous BMT, a variety of *ex vivo* procedures are used to destroy the malignant cells in the patient's marrow prior to reinfusion, including treatment with cytotoxic drugs, exposure to monoclonal antibodies that will attack tumor-associated antigens, or harvesting and introducing stem cells (cells from peripheral blood).

Patients (and their families) are faced with a number of stressors: a life-threatening illness, location of a suitable donor (for allogeneic transplants see Alby, 1991; Patenaude, 1990), a toxic treatment, and common and potentially fatal side effects (e.g., liver failure). There are many acute side effects as well (e.g., hair loss, mouth and gastrointestinal mucositis, infertility, skin breakdown, infection, pneumonia). Hospitalization is prolonged (often three to six weeks or longer) and it is generally spent in isolation (Alby, 1991; Baker et al., 1991; Winer & Sutton, 1994). Of course, in the end, the treatment can fail and the cancer persist or rapidly recur (Patenaude, 1990; Winer & Sutton, 1994).

The many difficulties—toxicity, uncertainty, illness and isolation, dependency, constant need for care, expense—all contribute to patients feeling out of control (helplessness), alone, anxious, and/or depressed (Alby, 1991; Altmaier, Gingrich, & Fyfe, 1991; Brown & Kelly, 1976). In attempting to cope, patients may be demanding, or the converse, withdrawn (Brown & Kelly, 1976; Patenaude, 1990). Psychological efforts have focused on providing support to patients, their families, and staff (Alby, 1991), and maximizing control for patients, such as making choices about the hospital environment whenever possible (Patenaude, 1990). For example, BMT rooms are often equipped with televisions/radios and weights and/or bicycles are provided for exercise as patients become stronger. Additionally, patients have been encouraged to bring personal items from home (e.g., pictures, photographs) to decorate their rooms. Increased medical complications, age, distance from home, and poorer pretransplant psychosocial adjustment are associated with the need for more intensive psychological consultation (Futterman, Wellisch, Bond, & Carr, 1991).

8.09.4.3.5 Treatment side effects

Important steps have also been made toward understanding the etiology and prevention of at least three common disease/treatment-related complications. First, appetite and weight loss are significant clinical problems for cancer patients susceptible to tumor-induced metabolism or taste changes, having tumor-related obstructions (often diagnosed as primary cachexia/anorexia), or receiving gastrointestinal-toxic chemotherapy or abdominal radiotherapy (secondary cachexia/anorexia). Malnutrition is associated with increased morbidity and mortality (Knox, 1991). Approximately 50% of the above patients will develop food aversions, and have two or three aversions to particular foods; common aversions involve protein sources such as meats, eggs, and dairy products (see Jacobson & Schwartz, 1993, for a review). In particular, learned food aversions due to chemotherapy appear to be robust, with rapid acquisition (usually after one to three treatments) and maintenance after long delays (e.g., 48 hours) between food intake and aversive reactions (nausea) from the drugs (Bernstein, 1986; Jacobson & Schwartz, 1993). Research in this area has pointed the way, for example, to interventions employing novel tastes or "scapegoat" foods (e.g., lemon-lime Kool-Aid, unusually flavored hard candies such as coconut; Jacobson & Schwart, 1993) to "block" conditioning to familiar diet items, reducing food and beverage intake prior to drug administration, and ingesting carbohydrate rather than protein source meals. While food aversions may not involve appetite or weight loss, patients may unknowingly develop aversions to their favorite foods and this can affect their daily routine and perceived quality of life (Jacobson & Schwartz, 1993; Knox, 1991).

Second, fatigue is a problem reported by the majority of patients receiving radio- or chemotherapy (Nail & King, 1987; Smets, Garssen, Schuster-Uitterhoeve, & deHaes, 1993). Fatigue, and related symptoms described by patients as tiredness, lack of energy, sleepiness, confusion, and poor concentration have been related to cancer morbidity and poor treatment compliance. Although a common experience, few studies have been conducted on the correlates of fatigue (see Irvine, Vincent, Bubela, Thompson, & Graydon, 1991, for a review; Pickard-Holley, 1991; see Smets et al., 1993, for a review). Irvine et al. (1991) note that research has not demonstrated consistent relationships between fatigue, anemia, sleeplessness, and/or psychological distress (e.g., negative mood/depression), but it appears that fatigue does reduce overall daily functioning. Psychological and behavioral interventions have focused on alleviating or increasing tolerance to fatigue through preparatory information on side effects and activity–rest cycle recommendations (e.g., naps in the afternoon; Nail & King, 1987; Smets et al., 1993), as well as other activity planning or coping efforts (e.g., planning/scheduling activities, decreasing nonessential activities, and relying on others for assistance as needed; Rhodes, Watson, & Hanson, 1988).

The expectation and/or experience of unpleasant side effects can compromise a patient's quality of life such that the patient may miss treatment appointments and be unwilling or unable to continue treatment, regardless of whether it is curative or palliative (Morrow & Hickok 1993; Richardson, Marks, & Levine, 1988). With noncompliance, the dosage of treatment may be reduced, which can, in turn, lower the cure rate. In short, noncompliance is a behavioral problem that can have a direct impact on the effectiveness of cancer therapy.

Noncompliance with treatment has been related to increased emotional distress (e.g., Gilbar & Kaplan De-Nour, 1989; Richardson et al., 1988), severity of treatment side effects (e.g., nausea and vomiting, Lewis, Linet, & Abeloff, 1983; Richardson et al., 1988), and lower income (Lebovits et al., 1990). Even when patients are responsible for self-administration of therapy, such as taking their chemotherapy at home in order to reduce the number of required, but inconvenient, hospital visits, their noncompliance may continue. One report of multidrug therapy with adults having hematologic malignancies indicated that self-reports (vs. sera reports) overestimated compliance by a factor of two (Richardson et al., 1987).

Psychological interventions have focused on a variety of methods to improve patient compliance, including appointment reminders, clearly written and specific treatment communications (Anderson & Kirk, 1982), home visits, and medication-taking shaping interventions (Richardson et al., 1987), as well as hospital interventions such as offering a tour of the oncology clinic, videotape presentations about the therapy, discussion/question sessions, and take-home information (Burish, Snyder, & Jenkins, 1991). Burish et al. and others (e.g., Nail & King, 1987; Rainey, 1985) suggest that preparatory information can improve coping with treatment.

Importantly, psychological interventions can reduce distress during and immediately following cancer treatments. We now present the findings from two illustrative studies. Cain, Kohorn, Quinlan, Latimer, and Schwartz (1986) compared individual and group therapy formats with 72 women with recently diagnosed gynecologic cancer or who were currently receiving therapy for such a cancer. The intervention had eight components including discussion of the causes of cancer at diagnosis, impact of the treatment(s) on body image and sexuality, relaxation training, emphasis on good dietary and exercise patterns, communication difficulties with medical staff and friends/family, and setting goals for the future to cope with uncertainty and fears of recurrence. The eight-session program was conducted during individual sessions conducted in the hospital or the woman's home or in weekly groups of four to six patients conducted at the hospital. Outcome measures were administered pre- and post-treatment and at a six month follow-up. Post-treatment analyses indicated all groups improved with time; however, anxiety was significantly lower for the individual therapy subjects only. Gains for the intervention subjects were more impressive with the six month follow-up data when there were no differences between the intervention formats, but both groups reported less depression and anxiety and better psychosocial adjustment (including health perspectives, sexual functioning, and use of leisure time) than the no treatment control group. Thus, the brief intervention, delivered either in individual or group format, appeared to be immediately effective, with gains enhanced during the early recovery months.

Edgar et al. (1992) provided a psychosocial intervention to 205 patients who were randomized into two groups: one group received the intervention soon after entering the study and the other group after a wait of four months. The majority ($n = 159$) of patients had been diagnosed with breast, colon, lung, uterine, or head and neck cancers. Both groups were assessed on depression, anxiety, illness worry, perceived personal control, and ego strength at entry into the study, and at 4, 8, and 12 month intervals. The intervention (comprising five one-hour sessions) focused on coping skills and included problem solving, goal setting, cognitive reappraisal, relaxation training, and, at four month intervals, workshops on healthcare information and available resources. While coping improved over the year for all patients, the later intervention group experienced lower levels of distress sooner than the group who had received the intervention earlier. Edgar et al. (1992) suggest that the delay in intervention may have been beneficial because it afforded patients the time to reduce feelings of being overwhelmed and they were, therefore, more ready to participate in the intervention. Additionally, data indicated that patients with lower ego strength and cancer diagnoses other than breast cancer reported greater distress and, therefore, particularly benefited from the intervention, while patients with higher ego strength tended to cope well regardless of the intervention. These and related data (e.g. Forester, Kornfield, & Fleiss, 1985; see Andersen, 1992, for a review) attest to the significant distress that occurs when patients are in the midst of coping with diagnosis and treatment. Importantly, impressive gains can be achieved by the end of the intervention and often these positive gains are stronger with continued follow-up. Again, these effects have been achieved with brief interventions.

8.09.4.3.6 Choosing cancer treatments

Psychological and behavioral data have been (and should continue to be) important to patients and physicians alike for making choices among comparable treatments. Treatments that result in less quality of life disruption often become standard treatment. The most obvious example of the importance of psychological data influencing cancer treatments was that documenting the more positive outcomes (e.g., feeling more attractive, fewer sexual difficulties) for women treated with breast-saving procedures (lumpectomy plus adjuvant radiation and/or chemotherapy) rather than modified radical mastectomy (e.g., Margolis, Goodman, & Rubin, 1990). Similarly, lower rates of erectile and ejaculation difficulties (e.g., 30% vs. 90%) are important reasons for some men to choose supervoltage irradiation rather than surgery for prostate cancer (radical prostatectomy; see Andersen & Lamb, 1995, for a review). Parallel treatment data are available for women with genital cancer including those with uterine disease (Andersen, Anderson, & deProsse, 1989a) or preinvasive vulvar disease (Andersen, Turnquist, LaPolla, & Turner, 1988). Additionally, Rathmell, Ash, Howes, and Nicholls (1991) suggest that unless a survival advantage is demonstrated, patients with advanced head and neck cancer may want radiotherapy alone vs. surgery plus radiotherapy, as the treatment combination is associated with poorer quality of life scores (e.g., psychological well-being, speech quality, ability to eat, levels of energy and activity).

8.09.4.4 Recovery and Long-term Survival

The most important cancer end points have been treatment response rates, length of disease-free interval, and survival. Yet, as the prognosis for some sites has improved, there has been increased attention to the quality of life, particularly for long-term survivors of cancer. The term "survivor" typically refers to individuals surviving at least five years, as the probability of late recurrence declines significantly after that time for most sites. As individuals recover and resume their life patterns, there may be residual emotional distress, with some difficulties which require continued coping, and even the appearance of still other problems (late sequelae). We will discuss each of these circumstances, and provide examples of both emotional and physical challenges which may confront the cancer survivor.

An investigation by Dunkel-Schetter, Feinstein, Taylor, and Falke (1992) sheds light on the strategies cancer patients use as they recover and resume their life activities. They studied coping patterns of 603 cancer patients. Patient diagnoses included breast cancer, gastrointestinal, circulatory or lymph, gynecological, and respiratory cancers, as well as others. The timing of the assessment ranged from initial diagnosis to more than five years post-treatment. Five coping patterns were identified: seeking or using social support, focusing on positive aspects, distancing, cognitive escape-avoidance (e.g., fantasizing or wishful thinking with fatalistic thoughts of poor outcomes), and behavioral escape-avoidance (e.g., social withdrawal, drug use). All patients used multiple coping strategies, but distancing was the most common. Unique patterns were found for subgroups. For example, individuals who viewed cancer as more stressful tended to use cognitive and behavioral escape-avoidance strategies, whereas patients reporting less distress relied on seeking or using social support, focusing on the positive, and distancing. Data such as these may have many uses, such as being used to tailor psychological interventions to patient subgroups (e.g., identifying those patients who are likely to use drugs/alcohol to cope).

Lingering emotional distress from the trauma of diagnosis, treatment, and, more generally, life threat, may occur for a small subset, 5–10%, of cancer patients. When pronounced, this long-term distress has been likened to post-traumatic stress disorder. In fact, having residual distress from the diagnosis and treatment of a life-threatening illness is included as one of the circumstances which may precipitate a *Diagnostic and statistical manual of mental disorders* (American Psychiatric Association, 1994) diagnosis of post-traumatic stress disorder. It is unlikely that such extreme distress occurs for the "average" cancer patient, and instead may only be a possibility for those who have undergone the most difficult of treatment regimens (e.g., BMT), multiple agent and/or lengthy chemotherapy regimens, as might be given to Stage III ovary patients, or those who undergo life-altering and/or disfiguring cancer treatments (e.g., limb amputations, pelvic exenteration, laryngectomies). As is the case with anxiety disorders, individuals with a prior history of traumatic stress might also be at heightened risk.

Secondly, some cancer survivors may need to cope with the expected, but nevertheless troubling, sequelae which may be consequences of the disease or treatment and be permanent. For example, coping with altered abilities (e.g., loss of natural speech following laryngectomy) or changes in organ functions (e.g., infertility) may require adjustment which demands new behaviors or emotions. Others may have to cope with losses (e.g., a sexual relationship that does not include intercourse). Thirdly, late side effects of cancer treatment, for example, a bowel dysfunction that is traced to pelvic radiotherapy, can occur and change health status as well as impact mood and coping.

Despite these possibilities, longitudinal data indicate that if the disease is controlled, by one year post-treatment the severe distress of diagnosis will have dissipated and emotions will have stabilized. The first longitudinal studies conducted in the UK for breast cancer patients indicated that by 12 (Maguire et al., 1978) and 24 months (Morris, Greer, & White, 1977) that approximately 20% of the patients had problems with moderate to severe depression in comparison to 8% of benign disease comparison subjects. However, controlled longitudinal studies of breast (Bloom, 1987; Vinokur, Threatt, Caplan, & Zimmerman, 1989) and gynecologic (Andersen et al., 1989b) patients conducted in the USA and replicated with data from The Netherlands (deHaes, van Oostrom, & Welvaart, 1986) have indicated no differences between the levels of emotional distress of women with cancer and either benign disease or healthy comparison subjects. Similar declines and lowered levels of distress have been found in retrospective (Cella & Tross, 1986) and longitudinal (Devlen et al., 1987) studies of Hodgkin's disease and non-Hodgkin's lymphoma patients. The consistency of findings for the studies conducted during the 1980s is important because it represents replications across site, and, to some degree, treatment toxicity. In sum, we preface the remaining discussion by noting that global adjustment problems do not occur for the majority of cancer survivors; a more likely scenario is the occurrence of problem areas.

Irvine, Brown, Crooks, Roberts, and Browne (1991) concluded in their review of survivorship following breast cancer that few patients experience long-term psychological distress, yet 20–30% will experience loss of roles (e.g., employment), decreased functional abilities, and problems with social relationships. Data on the adjustment of BMT survivors reveal a somewhat slower recovery (Syrajala, Chapko, Vitaliano, Cummings, & Sullivan, 1993). Comparison of BMT survivors and other cancer patients on maintenance chemotherapy indicated that psychological functioning was satisfactory for both groups when assessed three to four years postdiagnosis (Altmaier et al., 1991). However, when BMT patients were assessed sooner (two or four years post-treatment), they reported poorer physical functioning, greater impaired personal functioning (e.g., need for self-care assistance), and more relational problems (e.g., sexual difficulties) than individuals on maintainence chemotherapy (Altmaier et al., 1991). Also, there are data to suggest that there may be some risk of neuropsychological impairment from BMT procedures. Data from Andrykowski et al. (1992) suggest impairments in memory and higher cognitive processing, which may be a sequela of BMT, *per se*, or prior cancer treatments which precede BMT (e.g., cranial radiation, intrathecal chemotherapy). The many difficult aspects of BMT noted above (e.g., intensive chemotherapy, possible whole body irradiation, long recovery time, isolation) may account for this slowed and potentially more problematic recovery (see Andrykowski, 1994; or Winer & Sutton, 1994 for a review).

Data suggest that sexuality may be one dimension that is more likely to undergo disruption than other major life areas. All cancer patients with solid tumors (approximately 85% of adult patients) are vulnerable to sexual dysfunction. Across sites, estimates range from 10% (e.g., breast cancer patients treated with lumpectomy), 70–90% (e.g., women with vulva cancer treated with modified radical vulvectomy), to 100% (e.g., men with prostate cancer treated with radical prostatectomy), with the distribution skewed toward greater levels of disruption (see Andersen & Lamb, 1995, for a review). Among the hematologic malignancies, such as Hodgkin's disease, estimates are in the range of 20% (Andersen & Lamb, 1995). The data within treatment sites indicate that disease and treatment factors are the primary etiologies for sexual problems (e.g., gynecologic complications associated with long-term adjuvant tamoxifen therapy for breast cancer, Wolf & Jordan, 1992; female androgen deficiency syndrome resulting from cytotoxic agents and/or bilateral salpingo-oophorectomies, Kaplan & Owett, 1993). Controlled longitudinal studies of breast cancer patients (Maguire et al., 1978; Morris et al., 1977) and gynecologic cancer patients (Andersen et al., 1989a) have indicated that if sexual problems develop, they do so as soon as intercourse resumes, and, if untreated, they are unlikely to resolve (see Andersen & Elliott, 1994, for a discussion).

In addition to medical contributors, we have focused on identifying sexual relevant psychological factors in predicting risk for sexual morbidity. Specifically, sexual self-schema (self-concept) is a cognitive view about sexual aspects of oneself; it is derived from past experience, manifest in current experience, and it guides the processing of domain-relevant social information (Andersen & Cyranowski, 1994). The concept includes two positive aspects—an inclination to experience romantic/passionate emotions and a behavioral openness to sexual experiences and/or relationships; and a negative aspect—embarrassment and/or conservatism—which appears to be a deterrent to sexual expression. Using a measure developed for this purpose, the predictive power of sexual schema was examined in the context of risk for sexual morbidity following gynecologic cancer. Consistent with our definition of the construct, we anticipated that women with a negative sexual self-concept, in contrast to women with a positive sexual self-concept, would be at greatest risk for sexual difficulty. Negative sexual schema women would be expected to have more difficulties because they are, in general, less romantic/passionate in their emotions, less open to sexual experiences, and more likely to have negative feelings about their sexuality.

In a field test of sexual schema in the prediction of gynecologic cancer outcomes (Andersen, Woods, & Copeland, 1997), we assessed 62 women who were currently disease free but who received treatment from six months to five years previously for Stage I–II disease. Comparison subjects included 68 women seeking routine gynecologic care. Analysis of the quality of life data replicated earlier prospective longitudinal findings (Andersen, Andersen, & de Prosse, 1989a)—specifically, sexuality is the major life area of disruption for the survivor. For example, there were no differences between the groups in the areas of mental health (emotional distress, depression) or social functioning. In contrast, a comparison between the samples in terms of current sexual functioning found significant differences, with the cancer sample reporting lower levels of sexual behavior, sexual responsiveness, and global evaluations. We tested the utility of the schema construct with the cancer sample in the prediction of sexual responsiveness (e.g., desire, excitement, orgasm, and resolution) and sexual behavior (frequency of intercourse) with regression analyses. Sexual self-schema accounted for a significant and large portion of the variance (26%) in the prediction of current sexual responsiveness.

The high incidence of sexual and fertility disruption has, in part, been the reason for the concern over marital disruption among adult cancer patients. An early clinical study of women receiving radical mastectomy noted the realistic feelings of body disfigurement that both the women and spouses would feel—prompting sexual retreat, emotional estrangement, and, not surprisingly, marital disruption (Bard & Sutherland, 1952). Other concerns over the marriage originate from analyses of the interpersonal relationships, *per se*, (Wortman & Dunkel-Schetter, 1979). Despite the emotional distress and, for some, accompanying sexual disruption that couples experience, data from retrospective studies with comparison groups (Cella & Tross, 1986) and from the controlled longitudinal studies previously discussed indicate that the majority of marriages remain intact and satisfactory. These data are consistent with prospective studies showing that, when health problems arise for newly married couples, they are not among those problems precipitant to divorce (Bentler & Newcomb, 1978). However, multicenter studies have indicated that young survivors of childhood cancers are significantly less likely to marry, and once married they may be at greater risk for subfertility (Byrne et al., 1985, 1988; Teeter, Holmes, Holmes, & Baker, 1987).

Yet, the cancer experience is stressful for those closest to the patient (see Baider, Cooper, & Kaplan De-Nour, 1996, for a review), and the kin's distress may approach that of the patient's (Baider & Kaplan De-Nour, 1988; Cassileth et al., 1985). Family strain appears to be affected by illness variables (e.g., prognosis, stage/duration of illness, care-giving demands, patient's distress), family variables (e.g., age and gender of family members, socioeconomic status, other family stressors), and relational variables (e.g., quality of marriage, marital communication, family stage, and social support; see Sales, Schulz, & Biegel, 1992, for a review). Those couples in which the wife/mother has cancer and young children are still in the home may be at heightened risk for relationship difficulties (Vess, Moreland, & Schwebel, 1985). In addition, Ell, Nishimoto, Mantell, and Hamovitch (1988) found that those kin who were functioning poorly (e.g., lower perceived personal control, less adequate emotional support from close others, and greater stress unrelated to cancer) when the patient was diagnosed, or who lost personal and social resources during the patient's treatment and recovery, tended to function poorly at follow-up. In sum, a subset of partners and family members appear to be at psychosocial risk. For a review of strategies (focusing on information and support) that have been used to assist spouses of cancer patients cope with stress over the illness course, see Northouse and Peters-Golden (1993).

Finally, other, nonpsychological difficulties may occur following cancer, and these problems may have psychological concomitants (e.g., low self-esteem, perceived worthlessness). For example, it has been found that survivors of childhood or adolescent cancer are at risk of rejection from the armed services or college entrance and have difficulty obtaining health and life insurance (Teta et al., 1986). Job discrimination and insurance difficulties have also been reported by survivors of bone marrow transplantation (Wingard et al., 1991).

There have been few interventions targeted for cancer survivors *per se*. One such study was that by Telch and Telch (1986). They compared the effectiveness of coping skills instruction vs. supportive therapy for a heterogeneous sample of cancer patients on follow-up. An important research design aspect was the screening of the subjects, and only those with "clear evidence of psychological distress" were included in the trial. Both interventions were offered in a group format. Instruction in coping skills taught cognitive, behavioral, and affective strategies and included goal setting, self-monitoring, and role playing. Relaxation training and stress management skills were also included and patients provided ratings of their home practice. The group support intervention provided an environment for patients to discuss concerns but there was no specific agenda. Each group met for six weeks. Forty-one cancer patients completed the study. Analyses for the emotional distress data indicated that the coping skills group improved significantly across all measures, the support group improved on anxiety and depression only, but the no treatment control worsened and reported significantly more mood distress.

8.09.4.5 Recurrence and Death

Cancer recurrence is devastating; the magnitude of distress is even greater than that found with the initial diagnosis (Mahon, Cella, & Donovan, 1990; Thompson, Andersen, & DePetrillo, 1992), and studies contrasting cancer patients showing no evidence of disease with those receiving palliative treatment (e.g., Cassileth et al., 1985) have reported the greatest distress for those with disseminated disease (Bloom, 1987). Patients recently told of their cancer recurrence reported being less hopeful, more discouraged, having increased thoughts of death and dying as well as feelings of guilt and regret about their previous treatment decisions. In one study (Mahon et al., 1990), 45% of the patients indicated that they perceived their recurrence as "punishment." Therefore, difficult decisions (e.g., beginning a regimen that offers little chance for cure and has side effects vs. no treatment) are made in a context of extreme emotional distress and physical debilitation. However, the few studies of psychological interventions for adult patients have indicated that important emotional gains can be achieved during terminal stages (Linn, Linn, & Harris, 1982) and that children and adolescents, as well as adults, can make independent decisions about the continuation of therapy when death is imminent (Nitschke et al., 1982).

At this time of significant emotional turmoil and physical difficulty, psychological interventions appear to enhance the quality of life. One example is an investigation of a group support intervention for women with breast cancer conducted by Spiegel and colleagues (Spiegel & Bloom, 1983; Spiegel, Bloom, & Yalom, 1981). Women were randomized to no treatment or a group treatment intervention that included discussion of death and dying, family problems, communication problems with physicians, and living fully in the context of a terminal illness. The intervention subjects were also randomized a second time to two conditions: no additional treatment or self-hypnosis for pain problems (Spiegel & Bloom, 1983), which was incorporated into the support group format. All intervention groups met for weekly meetings for one year, for a total of 75 therapy hours. At the end of the first year the groups formally ended, but members could continue to meet as they wished or were able; some groups lasted for an additional two years. Eighty-six women, 50 intervention and 36 no treatment control, with metastatic breast cancer and referred to the intervention by their oncologist, participated. Following random assignment, there was subject loss (e.g., refusal, too weak, death) with the study beginning with 34 intervention and 24 control participants; however, the survival data are reported for the original sample of 86. Analyses indicated that the intervention group reported significantly fewer phobic responses and lower anxiety, fatigue, and confusion and higher vigor than the controls. These differences were evident at all assessments but the magnitude increased from 4 to 12 months. There was also a significant decrease in the use of maladaptive coping responses by the intervention group.

Regarding the findings from the hypnosis substudy, women receiving hypnosis within the group support intervention reported no change in their pain sensations during the year, while pain sensations significantly increased for the other women in group support who did not receive hypnosis. Similar findings were reported for pain suffering—a slight decrease for the women who also received hypnosis and a significant increase in suffering for the remaining intervention women. It is important to note that pain sensation scores for both groups were, however, significantly lower than those for the no intervention controls, suggesting that the hypnosis component provided an additive analgesic effect to other group treatment components. The most startling data from this project were reported in a survival analysis described at the beginning of the chapter. A variety of follow-up analyses, controlling for initial disease stage, days of radiotherapy, or use of androgen or steroid treatments were conducted and all indicated the same survival differences favoring the intervention participants. Unlike other studies, interventions for terminal patients tend to be intensive and lengthy, such as "several sessions" or "until death."

Finally, a frequent complication of disseminated disease is pain. Although it might be one of the first symptoms of cancer or be present when disease is localized, pain is more common and less controllable for those with metastatic disease (Ahles, Ruckdeschel, & Blanchard, 1984). Some 80% of patients with recurrent cancer report moderate to severe pain compared with 40% of earlier stage patients (see Ashburn & Lipman, 1993, for a review). The major cause of cancer pain, accounting for roughly 70% of the cases is due to direct tumor involvement (e.g., metastatic bone disease, nerve compression). Another 20–30% of cases are due to medical therapy (e.g., postoperative pain, radiation-induced pain). The remaining cases are individuals with pain problems unrelated to their cancer (e.g., osteoarthritis; Foley, 1985). Thus, the pain experienced by cancer patients can be any combination of acute malignant pain, chronic malignant pain, and/or chronic nonmalignant pain (Ashburn & Lipman, 1993).

As the pain experienced by each patient is variable (e.g., type, duration, resting vs. active, diagnosis/treatment factors), it is important that a pain assessment be completed before and during implementation of treatment for pain control (Ashburn & Lipman, 1993; Coyle, Adlehardt, Foley, & Portenoy, 1990). Besides pain-specific qualities and diagnostic/treatment considerations, other factors are also important in assessing the patient's experience of pain. For instance, pain is associated with depression, anxiety, and delirium (Massie & Holland, 1992), and may increase suicidal ideation (Coyle et al., 1990). If pain worsens or is difficult to control, quality of life deteriorates and emotional distress increases (Massie & Holland, 1992), physical mobility may lower (Ashburn & Lipman, 1993), and social interactions may decline (Strang & Qvarner, 1990).

The most difficult circumstance of pain control is when chronic pain accompanies disease progression. Treatment combinations of antitumor therapy, anesthetic blocks, and behavioral approaches are considered. Behavioral research has focused on assessment strategies (Daut, Cleeland, & Flanery, 1983; Keefe, Brantley, Manuel, & Crisson, 1985) and on pain reduction interventions, particularly hypnosis, to reduce pain (Spiegel & Bloom, 1983). When palliative therapy is of little use and/or brings further debilitation, psychological interventions may provide support and pain control and, secondarily, treat pain sequelae (e.g., sleep disturbances, reduced appetite, irritability).

8.09.5 CONCLUSION

Significant progress has been made in understanding the psychological, social, and behavioral aspects of cancer. There has been progress in prevention and control. Research on smoking prevention and cessation addresses the factor responsible for 30% of all cancer deaths. Similar efforts to encourage participation in screening and early detection programs for breast, cervix, skin, prostate, and colon and rectum cancers may also improve mortality rates.

More is known about the psychological processes and reactions to the diagnosis and treatment of cancer than is known about any other chronic illness. Breast cancer patients (see Glanz & Lerman, 1992, for a review) have been well studied, but other disease sites, men, and children, are becoming more commonly studied. Future research will probably test the generalizability of these descriptive data and formulate general principles of adjustment to illness. While providing estimates of the magnitude of quality of life problems, these data can be used for models that predict which patients might be at greatest risk for adjustment difficulties (see Andersen, 1996, for a discussion). The latter is an important step toward designing interventions tailored to the difficulties and circumstances of cancer patients.

The mental health community emphasizes the need to reduce stress and prevent deteriorations in quality of life for those with cancer. The importance of such efforts is underscored by three contextual factors. One, the stability of many cancer mortality rates, particularly those with the highest incidence such as lung and breast, makes it imperative that new, innovative treatments be developed to improve survival rates. Two, research has demonstrated that psychological interventions result in significant improvements in quality of life (see Andersen, 1992, for a review). Three, both qualitative (Maier, Watkins, & Fleshner, 1994) and quantitative (Herbert & Cohen, 1993a, 1993b) summaries of the psychoneuroimmunology literature conclude that psychological distress and stressors (e.g., negative life events, both acute and chronic) are reliably associated with changes—downregulation—in immunity. Thus, addressing the mental health needs of those with cancer will have important quality of life benefits and the possibility is raised of positive biologic (or health) consequences as well. Figure 1 provides a conceptual model of the psychological and behavioral factors and biologic mechanisms by which disease or health outcomes might be influenced. The majority of the paths move in one causal direction. We have discussed the importance of conceptual models in guiding future intervention research and in testing for any health benefits of psychological interventions (see Andersen et al., 1994).

A growing literature on the use of psychological interventions to improve the cancer patient's quality of life also exists (Andersen, 1992). The effectiveness of these interventions is robust, as they have reduced distress and enhanced the quality of life of many cancer patients differing on disease stage as well as disease site. Despite the challenges of studying these patients, well-controlled investigations have been conducted. Improvements in emotional distress are found at the end of the interventions with continued gains at follow-up. In addition, change in other areas—self-esteem/concept, death perceptions, life satisfaction, and/or locus of control—have been found. Important for quality of life, psychological interventions could also lower or stabilize pain reports. The positive outcomes for terminal patients are notable considering their worsening pain and/or increasing debilitation.

While there appear to be unique intervention components for different phases of the disease,

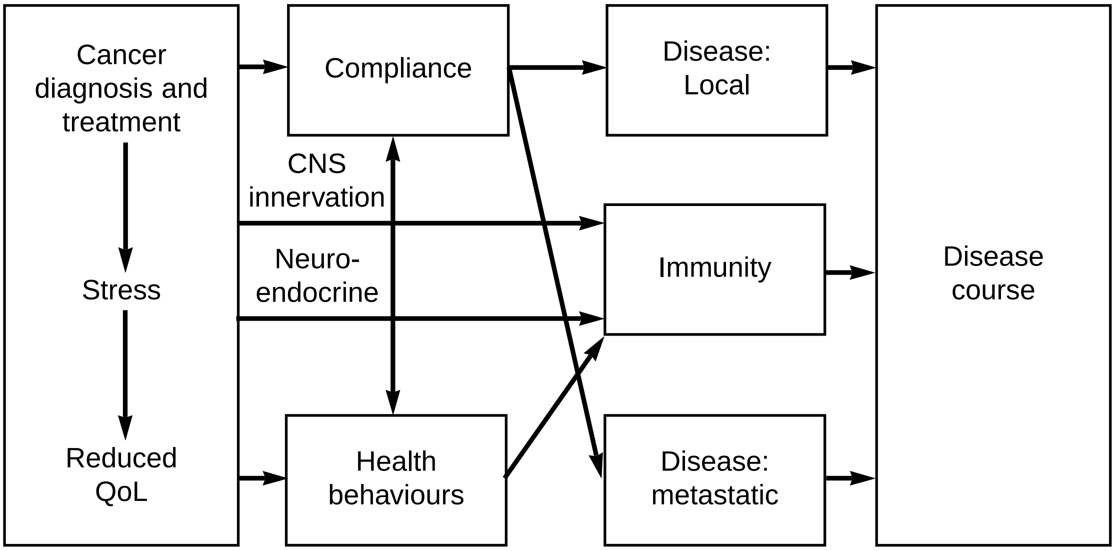

Figure 1 Theoretical model. A biobehavioral model of the psychological, behavioral, and biologic pathways from cancer stressors to disease course. CNS = central nervous system. From Andersen et al. (1994).

there are some commonalities. Therapy components have included: an emotionally supportive context to address fears and anxieties about the disease, information about the disease and treatment, behavioral coping strategies, cognitive coping strategies, and relaxation training to lower "arousal" and/or enhance one's sense of control. The descriptive data also highlight the need for focused interventions for sexual functioning, particularly those treated for gynecologic, breast, and prostate cancer, and the intervention studies attest to the effectiveness of these specific components. These various components appear more important to outcome than procedural variations. For example, therapy format, such as individual or group, appears to have little impact. Also, there were null findings for (group) interventions that included no structured content, suggesting that group support alone is insufficient to produce any measurable benefit (see Helgeson & Cohen, 1996, for a review).

How do psychological interventions achieve these effects? In large measure, the psychologic mechanisms may not be different from those operative in interventions designed for coping with other stressors. That is, confronting a traumatic stressor with positive cognitive states, active behavioral strategies and, eventually, lowered emotional distress may enhance one's sense of self-efficacy, feelings of control, and provide realistic stress appraisals of the disease or treatment process. Similarly for sexual interventions, information provides realistic expectations for sexuality and specific strategies to manage sexual activity when it is difficult or impossible. That the interventions produce more than situational improvement and may alter an individual's longer-term adjustment processes is suggested by data indicating that adjustment gains continue (and often increase) during the first post-treatment year. Immediate and longer-term psychologic changes may, in turn, increase the likelihood of changes in behavioral mechanisms, such as increasing the likelihood of adaptive health behaviors (complying with medical therapy; improving diet, exercise, etc.), to improving mental health directly, "adjustment" and, possibly, medical outcomes (e.g., disease-free interval). These data indicate that, increasingly, issues of quality of life are being raised, and positive results have been achieved by the behavioral scieces. But as with most issues, further commitment and action are needed.

8.10.1 INTRODUCTION

8.10.1.1 Pathogenesis of HIV Infection

The human immunodeficiency virus (HIV) is a retrovirus of the human T-cell leukemia/lymphoma line and is the causative agent of the acquired immunodeficiency syndrome (AIDS). (Although AIDS is believed to be caused by the human immunodeficiency virus-type 1 (HIV-1), we have for simplicity used the term HIV throughout this chapter.) A unique feature of HIV infection is that it can have a long asymptomatic phase lasting up to 10–15 years (Munoz et al., 1988) followed by the appearance of constitutional signs and symptoms of disease progression. In most people full-blown AIDS develops next (Kaplan, Wofsy, & Volberding, 1987), and even with aggressive and timely treatment, death often occurs a few years later (Lemp, Payne, Neal, Temelson, & Rutherford, 1990). A diagnosis of AIDS is made when a person shows laboratory-based signs of severe decline in the number of T-helper–inducer (CD4) cells ($< 200\,\text{cell}\,\text{mm}^{-3}$), or clinical signs consistent with the emergence of opportunistic infections and neoplasias. Some of these include: candidiasis of the esophagus, trachea, bronchi, or lungs; cryptoccosis; cryptosporidiosis with diarrhea persisting longer than one month; cytomegalovirus disease of an organ other than the liver, spleen, or lymph nodes; herpes simplex virus infection causing a mucocutaneous ulcer for longer than one month; Kaposi's sarcoma; primary lymphoma of the brain; pneumocystis carinii pneumonia; progressive multifocal leukoencephelopathy; toxoplasmosis of the brain; and a variety of other opportunistic infections and neoplasias. Since some infected people can remain free of clinical symptoms for a prolonged period of time and given that appropriate patient management can delay the onset of AIDS, it may be useful to view HIV as a chronic disease.

Many staging systems for HIV infection have been developed over the past decade (Walter Reed system, World Health Organization, and Centers for Disease Control), though the most widely accepted system used today is that developed by the Centers for Disease Control (CDC) in 1993. People with primary HIV infection often develop an acute mononucleosis-like syndrome about a month after initial infection (Tindall & Cooper, 1991). This period is associated with a high level of viral load or free virus released throughout the circulation (i.e., viremia) (Daar, Moudgil, Meyer, & Ho, 1991) which usually occurs 4–12 weeks after the onset of acute infection (Clerici, Berzofsky, Shearel, & Tacket, 1991). The virus becomes widely disseminated during this early stage of infection, suggesting that the course of infection may be influenced by the "seeding" of the virus throughout the lymph nodes and other immune system components (Tindall & Cooper, 1991). Even after this acute stage of the infection it appears that viral replication is not completely curtailed since it remains detectable in lymph nodes during the quiescent stages of the infection (Pantaleo, Poli, & Fauci, 1993).

A period of clinical, but not microbiological, latency lasting for a number of years follows the initial sequence of primary infection, viral dissemination, development of HIV specific immunity, and curtailment of extensive viral replication. Importantly, during the clinically latent period the disease is still progressing. This is observable in an increasing viral load, the depletion of CD4 cells in peripheral blood, and in the increasing proportion of HIV infected lymphoid cells (Pantaleo et al., 1993). It is generally accepted that the decline in CD4 cells leaves the infected person susceptible to a number of opportunistic infections and cancers characteristic of AIDS, though there is evidence that malfunctions in other aspects of immune functioning may also be associated with disease progression. Some of the more commonly observed infections include *pneumocystic carinii* pneumonia (PCP) cryptococcal meningitis, toxoplasmosis, and candida esophagitis (Kaplan et al., 1987). Many other diseases manifest in HIV-infected persons are caused by ubiquitous herpes viruses (e.g., cytomegalovirus (CMV) associated retinitis is a major cause of blindness in HIV-infected persons). HIV infected persons are also vulnerable to relatively rare cancers including Kaposi's sarcoma and Burkitt's lymphoma and, in women, cervical carcinoma. Interestingly these cancers are believed to be promoted by fairly common viruses as well (e.g., human papillomavirus types are associated with cervical neoplasia and squamous cell cervical carcinoma (Maiman & Fruchter, 1996). In contrast, it is rare that these viruses are successful in eluding the immune system for long enough to establish a clinical neoplastic process in healthy people, unless these people are undergoing pharmacologic treatments that suppress the immune system (Antoni, Esterling, Lutgendorf, Fletcher, & Schneiderman, 1995). HIV-infected persons are then extremely vulnerable to a wide range of pathogens normally controlled by the immune system and, with time, these individuals may contract a number of life-threatening diseases over the course of the infection. Because a person's awareness of their diagnosis and, more importantly, their symptom status may play an important role in determining their perceived psychosocial and physical burdens as well as their chosen coping strategies, this chapter shall later refer to different phenomenological stages of HIV infection tied to critical events as follows: the initial HIV seropositive diagnosis; the (post diagnosis) asymptomatic stage; the pre-AIDS symptomatic stage (formerly referred to as AIDS related Complex (ARC); and AIDS (often referred to as full-blown or frank AIDS).

Because there is no cure for AIDS, prevention is the major tool for limiting the spread of the disease. Primary prevention efforts use many behavioral change techniques, aimed at increasing availability and promoting use of condoms, and substance abuse management and treatment (Schneiderman, Antoni, Ironson, LaPierriere, & Fletcher, 1992). Many of these techniques are those that are commonly employed by health psychologists working in the area of risk management. Secondary prevention programs have also been undertaken to slow HIV spectrum disease progression. Because only a relatively small proportion of the one million people in the United States infected with HIV have AIDS (CDC, 1995) and because of the relatively prolonged period of time between the onset of infection and the development of AIDS (Munoz et al., 1989), there is a clear need to develop treatments to manage HIV spectrum disease and slow down disease progression. Much of this chapter will focus on such secondary prevention activities.

Many pharmacologic agents have been developed to manage symptoms and to slow HIV progression. These include such agents as pentamidine (to combat acute PCP and as a prophylaxic) and a large number of antiretrovirals, the most well-known being azidothymidine (AZT), to block the replication of HIV. To at least some extent advances in patient management have been successful in ameliorating symptoms and dealing with intercurrent illnesses (Longini, Clark, & Karon, 1993). In contrast, the benefits of antiviral therapies such as AZT, dideoxyinosine (ddI), and dideoxycytidine (ddC) appear to be only marginally effective and more controversial. In fact, in a letter to the *Lancet*, the Concorde Coordinating Committee (Aboulker & Swart, 1993) reported that although AZT modestly boosted the number of CD4 cells in the blood of asymptomatic patients, it did not delay progression to AIDS. Previous research had already shown that AZT only prolonged the life of HIV infected people for a few months (Fischl et al., 1987). The antiviral drugs also have undesirable physiological (e.g., bone marrow suppression, anemia, neutropenia; Richman, et al., 1987) and psychological (e.g., depression) side effects. We now know that using a single antiretroviral agent may lead to the development of AZT-resistant strains of HIV which are ultimately harder to treat; thus contemporary treatment approaches often focus on combination therapies (e.g., AZT and ddC). Newly emerging treatments such as triple combination therapy and protease inhibitors offer some hope that viral replication can be slowed more efficiently and with a lower likelihood of resistance or undue side effects (Lewin, 1996). However, we are now learning that the effectiveness of these newer regimens is critically dependent on the ability of patients to adhere to a rigid and demanding medication schedule. Failure to do so can substantially increase the risk of developing drug-resistant strains of the virus (Lewin, 1996; Schneiderman, Antoni, & Ironson, 1997).

8.10.1.2 Health Psychology and HIV Infection

Behavioral scientists focusing on HIV infection are usually involved in either primary prevention efforts (e.g., examining factors underlying risk behaviors that lead to infection in order to inform community-wide interventions and health policies) or secondary prevention efforts (e.g., examining factors contributing to the mental and physical health course of HIV-infected persons in order to develop clinical interventions). This chapter will focus on the role of health psychology in such secondary prevention efforts, though findings relevant to primary prevention efforts (e.g., predictors of sexual behavior and substance use) will also be addressed.

Managing HIV disease involves addressing psychosocial as well as biomedical issues (Antoni, Schneiderman et al., 1990; Schneiderman et al., 1994). The anticipation and the impact of HIV antibody test notification, for instance, is highly stressful (Ironson et al., 1990). Here, feelings of life-threat, doom, and anger are usually encountered as is the need to contemplate making major lifestyle changes (Christ & Wiener, 1985; Kaisch & Anton-Culver, 1989; Viney, Henry, Walker, & Crooks, 1989). Because of the large and accelerating number of people who are infected with HIV, there is a clear need to develop behavioral interventions to help them cope with the psychosocial aspects of their situation. There is also some evidence that improving psychological adaptation to HIV may have implications for physical health among infected individuals. Two areas that have been the focus of much health psychology research in HIV infection and AIDS examine how psychosocial factors such as distress states and depressive symptoms as well as certain risk behaviors might contribute to (i) the ways in which people adjust to the having HIV infection; and (ii) the actual health course of the infection.

Health psychological studies focusing on HIV and AIDS began in about 1987, coincident with the identification of HIV as the putative cause of many AIDS-related conditions that were emerging in clinics and hospitals around the world. At that time, behavioral scientists began studying the effects of psychosocial factors such as stressors and stress management interventions in people infected with HIV. The first major reason for this health psychological research concerned the issue of psychological adjustment. HIV infection presents multiple burdens at the psychological and physical levels, thereby creating a state of chronic stress that may overwhelm an individual's coping resources, thus greatly impairing their ability to emotionally adjust to what will likely be a long journey. Accordingly, it was reasoned that HIV infected individuals are among the groups who might benefit substantially from interventions that teach them to cope with the chronic demands that many people will never have to face. By learning how stress-reducing psychosocial interventions help such people adapt, adjust, and adhere to various lifestyle changes health psychologists gain insight into ways to facilitate the coping process in people facing this life-threatening condition as well as other chronic diseases (for reviews see Antoni, 1991; Ironson, Antoni, & Lutgendorf, 1995; Lutgendorf, Antoni, Schneiderman, Ironson et al. 1994; Schneiderman et al., 1994).

A second major reason for examining the effects of psychosocial factors in this population follows from a conceptualization of HIV infection as a chronic disease whose clinical course may be affected by multiple behavioral and biological factors (Antoni, Schneiderman et al., 1990). As in the case of other chronic diseases, HIV infection is characterized by a disorder in one or more bodily systems wherein signs and symptoms of the disorder are clinically manifest across long periods of time as a function of the degree of disorder in the bodily system(s) affected (e.g., immune system impairment). People with HIV infection become ill or die from the complications of their chronic disease not the disease itself. Just as diabetics who are unable to maintain their blood glucose levels within a certain range may develop kidney disease or suffer heart attacks, HIV-infected people who are unable to retain adequate immune system functioning necessary for surveillance of pathogens go on to develop the life-threatening infections or cancers that characterize full-blown AIDS.

8.10.1.2.1 Psychoneuroimmunology research and HIV infection

To the extent that HIV infection increases distress levels (Antoni, Schneiderman et al., 1990; Kaisch & Anton-Culver, 1989; Viney et al., 1989), which in turn have been shown to influence the immune system (Calabrese, Kling, & Gold, 1987; Ironson et al., 1990; Irwin, Daniels, Bloom et al., 1987; Kiecolt-Glaser et al., 1987), it is plausible that behavioral interventions that decrease distress may beneficially impact immune status and possibly health status in HIV-infected people. Because the degree to which the immune system becomes disordered seems to be the strongest predictor of the progression to HIV-related symptoms and death, much biomedical research has been focused upon ways to either slow the growth of the virus or slow the decline of the immune system by modulating the function of its cells. Psychoneuroimmunologic (PNI) research examines ways in which psychosocial influences such as stressful life events, distress states, and stress reducing techniques—all of which may contribute to successful adjustment to HIV infection—modulate immune system functioning and, ultimately, disease course. Applying these ideas from the point of view of a chronic disease model, to the extent that health psychology interventions modify psychosocial factors such as risk behaviors (unprotected sex, alcohol and drug abuse), emotional distress, maladaptive coping strategies, and social isolation, it might also modulate biological factors such as certain endocrine and immune system components. By diminishing the impact of psychosocial and behavioral factors on the immune system, the individual might retard the onset of disease complications by maintaining immunologic status (e.g., by preserving an adequate number of T-helper cells and/or maintaining the functioning of surviving immune cells) within a range necessary to defend against certain infections and cancers.

There are many studies relating psychosocial and behavioral factors to the immune system in a wide collection of species using an even wider number of different experimental paradigms. This area is marked by significant agreement and disagreement about the ways in which a wide range of factors impact the immune system in healthy animal and human populations. Clinical researchers have attempted to translate many of these findings into the clinical arena in order to classify how psychological phenomena such as self-efficacy and sense of control, coping strategies, social support, and emotional states such as depression—all reasonable targets of psychological interventions—contribute to impairments in the immune systems of HIV infected individuals (e.g., Antoni, 1990; Solomon, Kemeny, & Temoshok, 1991). Given existing evidence that experimentally induced and naturally occurring stressors, perceived loss of control, social isolation, and depression are related to decrements in the numbers and functions of immune cells known to be altered by HIV infection, it can be reasoned that these psychosocial and behavioral factors might influence immunologic status and, possibly, disease course in HIV-infected individuals. Similarly, stress management interventions that target these factors might provide both psychological and physical benefits for infected people, especially for those in the early stages of this chronic disease before the virus has established a stranglehold on the immune system and other physiological regulatory processes.

This line of reasoning can be operationalized in the context of HIV infection as follows: because CD4 cells are depleted in the advancing stages of HIV infection (Klimas et al., 1991), increases in qualitative aspects of HIV itself (e.g., mutation and replication rate) (Panteleo et al., 1993) and of lymphocytes (e.g., proliferation [growth and reproductive abilities], and cytotoxicity [recognition and killing abilities]) might be important in predicting those HIV seropositive individuals who do and do not develop opportunistic infections quickly. The ability of lymphocytes to multiply when challenged by antigens, often evaluated using tests of lymphocyte proliferative responses to plant mitogens such as phytohemaglutinin (PHA), concanavalin-A (conA), or pokeweed mitogen (PWM), may compensate to some degree for the smaller number of CD4 lymphocytes available as the disease progresses. Innate immune functions such as natural killer cell cytotoxicity (NKCC), a largely CD4-cell independent function, may also compensate in conferring protection against extant viral infections. For instance, herpes viruses such as Epstein Barr virus (EBV) or herpes simplex virus (HSV) are often poorly controlled in the context of HIV-induced defects in CD4 cell-directed cytotoxic function (Biron, Byron & Sullivan, 1989; Habu, Akamatsu, Tamaoki & Okumura, 1984, Bancroft, Shellam, & Chalmer, 1981; Bukowski, Warner, Denner & Welsh, 1985). It is plausible that NKCC, which may be partially preserved in HIV infection, may help to survey and control these and other infections in the HIV-infected host. Conversely, stress-induced impairments in NKCC may permit herpes virus reactivation to go unchecked in HIV-infected individuals (Glaser & Kiecolt-Glaser, 1987) with subsequent effects of HIV replication and progression to AIDS (Carbonari, Fiorilli, Mezzoroma, Cherchi, & Aiuti, 1989; Rosenberg & Fauci, 1991). Because several herpes viruses are known to have immunosuppressive effects, in and of themselves, reactivation of these viruses could have implications for compounding HIV-induced immune system decrements and, possibly, disease progression (Griffiths & Grundy, 1987).

Implicit in much PNI research is the notion that psychosocial factors relate to immune system changes by way of stress- or distress-induced changes in hormonal regulatory systems resulting in neuroendocrine elevations and imbalances (Maier, Watkins, & Fleshner, 1994). There are several neuroendocrine substances known to be altered as an function of an individual's appraisal (i.e., controllable vs. uncontrollable) of and coping response (i.e., active vs. passive) to stressful stimuli that have also been shown to impair certain components of the immune system. Some of these hormones, including those produced by the adrenal gland, are also known to be dysregulated in depressed individuals (Calabrese et al., 1987) and those reporting significant degrees of loneliness (Kiecolt-Glaser et al., 1984). Given that uncontrollable stressors, perceived loss of control (similar to low self-efficacy), and social losses such as divorce and bereavement have been related to alterations in some of these immunomodulatory hormones, it has been reasoned that some PNI relationships might be mediated, in part, by neurohormonal changes that are linked to an individual's appraisals of and coping responses to environmental burdens (for reviews see Antoni, Schneiderman et al., 1990 and Schneiderman et al., 1994). Although many different neurotransmitters, neurohormones, and other peptides have been studied as potentially important mediators of stressor-induced immunomodulation, two well-delineated "stress response pathways," the hypothalamic–pituitary–adrenal (HPA) axis and the sympathetic adrenomedullary (SAM) system, have received the most focus.

The HPA axis is a complex system that is regulated by several integrated central nervous system and peripheral mechanisms, a regulation that may be disrupted at several levels in depressive illness and other affective distress states (Amsterdam, Maislin, Gold, & Winokur, 1989). Several of these HPA axis abnormalities gradually normalize with clinical improvement in depression (Greden et al., 1983; Amsterdam, Lucki, & Winokur, 1985). Because immunologic function is impaired by cortisol (Plaut, 1987) in humans, immunologic correlates (especially blastogenesis and NKCC) of depressed states have been studied extensively. Despite the conclusive evidence for immunologic effects and neuroendocrine changes in depression, the exact mechanisms involved are lacking (Stein, Miller, & Trestman, 1991). However, it has been shown that glucocorticoids enhance HIV replication (Markham, Salahuddin, Veren, Orndorf, & Gallo, 1986), are immunosuppressive (Cupps & Fauci, 1982), and accompany affective disorder (Gold et al., 1986) and stressful experiences (Borysenko & Borysenko, 1982; Jacobs et al., 1986). On the other hand, one study found that 24 hour urinary-free cortisol levels were not related to CD4 (or CD8) cell counts in HIV positive individuals (Gorman et al., 1991). However, this does not preclude the possibility that distress or depression-associated cortisol elevations impact immune function (e.g., NKCC) in HIV-infected individuals and that such functional changes might relate directly to HIV disease progression by way of impaired surveillance of latent viruses and other pathogens.

A separate, but related neuroendocrine response system, the SAM system, is also activated during stressful circumstances (e.g., bereavement) and releases norepinephrine (NE) and epinephrine (E). Lymphocytes have beta-adrenergic receptors (Plaut, 1987), and behavioral stressors (Manuck, 1991; Antoni, Rodriguez, Starr et al., 1991; Naliboff et al., 1991) increase CD8 counts and may induce cyclic AMP-mediated suppression of lymphocyte and natural killer (NK) function (Plaut, 1987). Activation of both the HPA axis and the SAM system, which may interact (Axelrod & Reisine, 1984), during exposure to chronic uncontrollable stressors, could adversely affect immunologic status (Cupps & Fauci, 1982; Maier et al., 1994; Roszman et al., 1985). These neuroendocrine patterns may also be displayed when an individual is exposed to uncontrollable chronic stressors, has inadequate social support, and uses denial/avoidance coping strategies (Antoni et al., 1990; Schneiderman et al., 1992). If depression and uncontrollable stressors are associated with impaired immunologic function mediated by neuroendocrine changes in HIV-infected individuals, and if intervention-associated decreases in depressed mood help to normalize neuroendocrine functioning in this population, then such interventions may concurrently act to attenuate neuroendocrine-associated immunosuppression.

Putting all of this information together it can be hypothesized that stressful events or burdens that are interpreted by HIV-infected individuals as beyond their control might lead to social isolation, loneliness, anxiety, and depressed affect which might accompany alterations in some neurohormones (e.g., peripheral catecholamine and cortisol elevations) due to sympathetic nervous system (SNS) activation and dysregulation of the HPA axis. These neuroendocrine changes may also be accompanied by changes in the immune system (redistribution of lymphocytes and decrements in functions concerning lymphocyte proliferation and NKCC) via interactions among neural and neuroendocrine signals at the immune cell membrane, intracellular cyclic nucleotide activation, and the production of cytokines such as interleukin (IL)-I and II, and γ-interferon (γ-IFN). Since these structural (cell counts) and functional (proliferation and cytotoxicity) aspects of the immune system are known to decline progressively across the course of HIV infection (Panteleo et al., 1993), it can be further hypothesized that superimposed stressor-induced changes in the functioning of the immune system may increase the rate at which infected people develop clinical symptoms such as opportunistic infections and neoplasias. This model prescribes at least two sets of related targets for intervention: psychosocial experiences and pathophysiological processes (see Figure 1) (for details see Schneiderman et al., 1994).

8.10.2 PREDICTING ADJUSTMENT TO HIV INFECTION

8.10.2.1 Psychological Challenges in HIV Infection

A diagnosis of HIV seropositivity is the beginning of a long road of challenging life events and extraordinary personal changes that can overwhelm even the most psychologically well-adjusted individuals. One unique aspect of HIV infection is that it is a chronic physical disease embedded in an atmosphere of multiple chronic psychosocial and physical demands and burdens. From a health psychology perspective, it is plausible to hypothesize that disease-related and external "life stressors" operate interactively and that success at managing one can influence the course of the other. To test these types of hypotheses behavioral researchers have for years been examining associations between the occurrence of stressful life events and alterations in people's resiliency or susceptibility to a wide variety of pathogenic processes underlying chronic diseases such as coronary heart disease, diabetes mellitus, rheumatoid arthritis, and several types of cancer. In addition to studying the impact of stressful events, health psychology researchers, since the mid-1970s, have also focused on the role of stress "moderating" psychosocial variables (e.g., personality characteristics and social support) and

psychosocial interventions (e.g., stress management) that might reduce the negative health influences of stressors in medically vulnerable populations such as those recovering from myocardial infarction or taxing treatments for some types of cancer.

Because more effective medical treatment for HIV infection is becoming available, there is now a fast-growing population of infected individuals who are coping with the complex and multiple psychosocial demands of a chronic life-threatening illness (Antoni, 1991). Homosexual men comprise a large majority of HIV-infected individuals in the United States. Today, however, an increasingly large percentage of HIV-infected people are heterosexual male drug users and women (Centers for Disease Control, 1995). Many of the people who are infected face lifestyle-associated social stigmas in addition to the direct burdens of the HIV infection. They endure many of the psychosocial phenomena previously associated with impairments in the immune system. Some of these changes include overt signs of progressive physical deterioration (Redfield & Burke, 1988), chronic legal problems (Blendon & Donelan, 1988; Ginzburg & Gostin, 1986; Walkey, Taylor, & Green, 1990), astronomical health-care costs (Bloom & Carliner, 1988), and multiple losses due to AIDS deaths (Martin, 1988)—all of which can be characterized as severe, chronic, uncontrollable, and unpredictable stressors. At the initial onset of HIV-related signs and symptoms these individuals may be overwhelmed and socially isolated, and may employ maladaptive coping strategies such as denial/avoidance possibly resulting in an increased likelihood of depression and distress, and perhaps sexual risk behaviors and substance use—all of these are potentially associated with changes in immunologic status (Antoni, 1991).

Since HIV infection is a chronic, progressive disease with an uncertain clinical course lasting up to 10–15 years, affected individuals must develop lifestyle changes, effective coping strategies, and, often, new social networks to meet their daily needs for hope, strength, and growth. Adjusting to a long-term progressive lethal illness entails addressing issues such as changes in self-expectations and preparation for death. These are, indeed, some of the central tasks in this stage of HIV infection (Hoffman, 1991; Lutgendorf, Antoni, Schneiderman, & Fletcher, 1994). A very tangible issue is that employment status often changes dramatically at this point in the disease (Chuang, Devins, Hunsley, & Gill, 1989; Dilley, Ochitil, Pert, & Volberding, 1985). One study reported that the average monthly income of patients with AIDS or ARC had fallen by an average of $1000 per month since their diagnosis (Ellerman, 1989). Intermittent episodes of PCP are highly associated with diminished abilities to maintain employment (Wachtel et al., 1992). Change in employment status can pervade many areas of life—loss of sources of social support, identity, income, and medical insurance—that, in turn, can deplete one's resources for dealing with the demands of the illness (Lutgendorf, Antoni, Schneiderman, Ironson et al., 1994).

Even for those who are successful at mustering the energy and resources for taking this journey, there still remain critical stressor events—emergence of new symptoms, development of resistance to a successful drug regime, loss of health insurance benefits, deaths of friends, rejection from family members, etc.—which can trigger lapses into depression, anxiety, and other distress reactions on the one hand and negative health behaviors on the other. Such lapses, if severe and unremitting, may contribute to a negative health course by way of increased mental health problems (Cleary et al., 1988; Jacobsen, Perry, & Hirsch, 1990) and acceleration of disease progression through PNI processes. If so, then psychosocial interventions may be capable of reducing the frequency and severity of these lapses with the accompanying effect of improving quality of life, reducing immunologic perturbations, and slowing the progression of the infection.

Some of the mechanisms that could mediate the effects of stress management intervention on the course of HIV infection have been proposed (Antoni, Schneiderman et al., 1990). According to this model, cognitive behavioral stress management (CBSM) interventions such as relaxation training and cognitive restructuring may reduce anxiety, depression, and social isolation by way of their ability to increase a sense of control, self-efficacy, and self-esteem. These psychological changes may also be accompanied by decreases in peripheral catecholamines and cortisol via decreases in sympathetic activation and improved regulation of the HPA axis, respectively. These neuroendocrine changes may, in turn, be associated with a partial normalization of immune system functions such as lymphocyte proliferation and NKCC that facilitate efficient surveillance of pathogens. To the degree that such a normalization of stress-associated immune system decrements can be achieved by stress management techniques, then any contribution of stressor and stress responses processes to acceleration of disease and expression of clinical symptoms might be forestalled or minimized.

It is arguable that such interventions can be targeted first to some of the more prevalent psychosocial and behavioral sequelae that HIV-infected people may face at various points in the disease process and some of the potentially changeable cognitive, affective, behavioral, and social factors that may aggravate or forestall these phenomena. Some of the most well-established sequelae include distress states, depressive symptoms, and negative health behaviors.

8.10.2.2 HIV-associated Psychosocial and Behavioral Sequelae

8.10.2.2.1 Distress and depression

HIV-infected persons appear to be at somewhat increased risk from *DSM-IV*-Axis I affective and adjustment disorders, and many suffer significant subclinical distress reactions following the initial news of an HIV seropositive diagnosis (Cleary et al., 1988; Jacobsen et al., 1990; Rabkin, Wagner, & Rabkin, 1996). Among diagnosable reactions, adjustment disorder with depressed mood may be the most common presenting complaint with major depressive disorder being far lower in prevalence (Perkins, Stern, Golden et al., 1994; Rabkin et al., 1996; Williams, Rabkin, Remien et al., 1991). One study found that the suicide rate among HIV-infected men may be up to 36 times that of age-matched uninfected men (Marzuk et al., 1988; Rundell, Paolucci, & Beatty, 1988), supporting the view that depressive symptoms are a common sequel to an HIV diagnosis and especially in those with a prior history of depression (Rabkin, Rabkin, Harrison, & Wagner, 1994). Pharmacologic treatments for depression such as imipramine and serotonin reuptake inhibitors have been shown to be safe and effective with HIV-infected samples (Rabkin et al., 1996). Newer work suggests that other biological approaches such as testosterone replacement therapy may also offer antidepressant effects (Rabkin et al., 1996). The coexistence of feelings of life-threat, doom, anger, and responsibility for making immediate lifestyle changes following a seropositive diagnosis (Christ & Wiener, 1985; Kaisch & Anton-Culver, 1989; Viney et al., 1989) suggests that psychosocial interventions that provide support, teach coping strategies, and offer the opportunity for mastery experiences may also be beneficial. Such interventions may also help these individuals to ventilate feelings such as anger (Miller, 1988) and manage anticipatory grief over the expectation of loss and death (Cohen, 1990; Pickrel, 1989). To the extent that HIV infection constitutes a chronic long-term disease, it is arguable that psychosocial intervention plays a key role in the treatment of HIV-infected persons. We have reasoned that all of these putative intervention effects are likely to be facilitated within a supportive group environment (Antoni, Schneiderman, & Ironson, in press).

Some of the evidence supporting the possible psychological benefits of a cognitive-behavioral treatment orientation for HIV-infected individuals comes from the patterns of results emerging from natural history studies conducted since the mid-1980s. For instance, there is growing evidence that the ways in which individuals cognitively and behaviorally cope with HIV-related stressors can influence their ability to establish psychological equilibrium at least within a given stage of the infection. In a community sample of 208 HIV-positive and HIV-negative, successful, and well-educated gay men, the coexistence of high levels of faith in the future and low levels of syndromal disorder or depressive symptoms (Rabkin, Williams, Neugebauer, & Goetz, 1990) suggested that interventions capable of instilling hope and self-efficacy may facilitate psychological adjustment. There is evidence that these "moderator" variables are not unique to gay men. Psychosocial characteristics of HIV-positive hemophiliacs related to elevated depression and distress included (i) a previous history of premorbid psychiatric disturbance/distress, (ii) experiencing recent life events involving loss, (iii) low social support from spouse, family, and friends, and (iv) a poor sense of mastery over life (Dew, Ragni, & Nimorwicz, 1990). Although based on a small heterosexual sample and a cross-sectional design, this work suggests the importance of uncontrollable loss-oriented life stressors, social isolation, and a lack of self-efficacy as deterrents of psychological adjustment to HIV infection.

While the psychosocial sequelae of HIV infection are reasonably well-documented for male samples, far less is known about what women experience during the course of this disease. Such information is imperative given the fact that the incidence of AIDS has increased at a faster rate for women than for any other subgroup in the population of the United States (Carpenter, Mayer, Fisher, Desai, & Durand, 1989; CDC, 1995a). AIDS incidence data through June 1996 indicates nearly 20% of all new AIDS cases are women (CDC, 1995b). AIDS cases and infected and at-risk women are disproportionately represented among minority populations, especially Blacks (Antoni, Schneiderman et al., 1992; CDC, 1995b). Young, Black American, low socioeconomic status (SES) women have been characterized as a group experiencing the triple stigmas of race, class, and gender, prior to the addition of the burden of HIV seropositivity (Quinn, 1993) as well as multiple chronic daily stressors (Freudenberg, Lee, & Silver, 1989; Mays & Cochran, 1988). These stressors include drug and alcohol dependency, poor social networks, medical problems, financial problems, overburdened public clinics, lack of transportation, and inaccessibility of child care, all potentially fueling a general feeling of helplessness and powerlessness (Quinn, 1993).

These stressors may be compounded even more by pregnancy (Antoni, Schneiderman et al., 1992). Relevant stressors here include the decision to abort or continue pregnancy to term, fears of becoming too ill to provide for offspring, and preparing older children for life as orphans. Seropositive mothers with unprotected partners are also likely to face rejection by the father of their children, resulting in emotional and financial isolation at a time when these women are most in need of support. Conversely, HIV seropositive women may react to an infected partner with self-isolation, both of which are likely to leave her and her offspring alone. If both mother and child are seropositive, the lack of emotional and financial support could make the situation even worse. Thus, the risk for significant emotional problems in HIV-infected mothers is obvious. It is critical that future work focus on factors contributing to depressive symptoms and mental adjustment in these growing populations of HIV-infected persons so that effective interventions can be developed.

8.10.2.2.2 Risk behavior and substance use

In addition to the influence of mood disturbances, psychosocial adjustment to HIV may be intimately related to negative health behaviors. In fact, certain negative health behaviors may show a bidirectional relationship with depression and distress levels. Two such negative health behaviors that are salient in the context of HIV infection are sexual risk behaviors and substance use. It is known for instance, that depressed people are often more likely to engage in risky (unprotected) sexual behaviors (Gold & Skinner, 1992; Kelly et al., 1993) and substance abuse (Rabkin et al., 1996). Beyond the fact that these two sets of behaviors are associated with transmission of the virus, it is also well known that they occur at very high rates in persons who are having difficulty dealing with being HIV-infected.

Despite reductions in sexual risk behaviors among urban gay men since 1987, a significant number continue to engage in unprotected anal intercourse (Martin, 1989), the sexual activity that carries the highest risk for HIV infection in gay men (Kingsley et al., 1987). Importantly, as many as 15% of those gay men who modified their sexual behaviors in the early years of the AIDS crisis have relapsed to unsafe sexual activities (Coates, 1991). One important factor that may influence such risk-taking behavior is the use of alcohol and drugs during sex (Martin, 1990b). The prevalence of alcohol abuse in the gay community is significantly higher (30%) than for the general population (5–10%) (Fifield, 1975; Lohrenz, Connelly, Coyne, & Spare, 1978; Martin, 1990b). Importantly, alcohol and drug use is strongly asociated with sexual behaviors and may determine adherence to safer sex guidelines in gay men (Martin, 1990b) as well as other populations who are at risk from HIV infection (Lollis, Antoni, Johnson, Chitwood, & Griffin, 1995; Lollis, Johnson, Antoni, & Hinkle, 1996). Finally, depressive symptoms may be more likely to occur in HIV-infected men and women who are substance abusers, especially those who are injection drug users (IDUs) (Rabkin et al., 1996). Thus, chronic depressive symptoms, substance abuse, and unprotected sexual behaviors may be highly interrelated and self-perpetuating.

Psychological factors related to the adoption and maintenance of reduced sexual risk behaviors include self-efficacy for safe sex, having alternative coping strategies for dealing with high-risk sexual impulses, and possessing skills for negotiating with interpersonal contacts (Kelly & St. Lawrence, 1988; McCusick, Hortsman, & Coates, 1985), while similar constructs such as condom efficacy and perceived vulnerability have been shown to predict sexual risk behaviors in injection drug users (Lollis et al., 1995). Denial of virulence and denial of personal responsibility, and frequent drug and alcohol use preceding sex (which are likely to facilitate one another) are also associated with continued high-risk behavior (Martin, 1990b). Specifically, Martin (1990b) found consistent associations between drug use (marijuana, inhaled nitrates, cocaine, hallucinogens, barbituates, and amphetamine) and unprotected insertive and receptive anal intercourse among 604 urban, middle-class gay men in the year prior to their development of AIDS. Cessation of drug use with sex predicted subsequent lower rates of unprotected anal intercourse (Martin, 1990). Thus, one way to intervene to reduce high-risk sexual behaviors may be to modulate drug and alcohol use perhaps by improving the ways individuals manage HIV-related stressors. Among 624 gay men, two categories of life stressors—deaths of loved ones due to AIDS and fear of illness and one's own death due to HIV infection—were associated with high-risk sexual behaviors and drug and alcohol use as well as psychological distress (Martin, 1989). Perceived self-efficacy and social support have also been shown to be critical for maintaining adherence to safer sex guidelines (Stall, Coates, & Hoff, 1988). Thus, among HIV-infected individuals, in addition to being associated with depressive symptoms, low self-efficacy, social support losses, and denial coping strategies may relate to the onset and maintenance of substance use and sexual risk behaviors and these may all be interrelated.

The role of ethnic, racial, cultural, and religious factors in influencing sexual behavior patterns is also an important consideration (Mays & Cochran, 1988); hence sociocultural influences on risk behavior reduction need to be understood. For poor ethnic minority women who are at risk of HIV infection or are already infected, the risk of AIDS is only one risk in a long list of multiple risks that are prevalent in daily existence. The key to behavior change is where in this list the women place the relatively longer-term consequences of AIDS-related risk behavior in relation to the short-term consequences of the risks of daily life (e.g., safety, food, shelter, human contact). From this vantage point, behavior change specialists need to be aware of more immediate survival needs which, if met, can provide the opportunity for professionals to educate and intervene effectively. Within this deeper understanding of the sociocultural milieu is the knowledge that the pervasive powerlessness experienced by disadvantaged women at risk may lead them to disengage from attempts at coping when informed about risk behaviors.

8.10.2.3 Psychosocial Factors Predictive of Depression and Risk Behaviors in HIV Infection

There is good evidence suggesting that the risk of depressive symptoms in HIV-infected persons is strongly tied to a prior history of depression (Rabkin et al., 1994). Other risk factors include a family history of depression, alcohol abuse, other substance abuse, and social isolation (Rabkin et al., 1996). There are also several psychosocial events that may follow the onset of initial HIV diagnosis and related symptoms (Antoni, Baggett et al., 1991; Schneiderman et al., 1992) and these may predict an increased likelihood of depression and distress, sexual risk behaviors, and substance use. These include: chronic, uncontrollable, and unpredictable stressors such as treatment nonresponsiveness and side effects, disease recurrence, stigmatizing behaviors, and medical costs (Blendon & Donelan, 1988; Bloom & Carliner, 1988; Ginzburg & Gostin, 1986; Redfield & Burke, 1988; Walkey, Taylor, & Green, 1990). Inability to cope with these mounting stressors may bring about a loss of self-esteem and self-efficacy, feelings of helplessness and hopelessness, depression, and an increase in maladaptive, potentially self-destructive negative health behaviors. The combination of uncontrollable life stressors and feelings of helplessness may increase cognitive and emotional burdens (Noh, Chandarana, Field, & Posthuma, 1990) that may overwhelm premorbid coping strategies such as active problem-solving and positive reframing resulting in the use of denial/avoidance coping strategies or giving up entirely. Loss of familiar sources of social support due to deaths of close friends (Martin, 1988), the infected person's own desire for social insularity and the avoidance by acquaintances and significant others following disclosure of homosexual orientation (Beckett & Rutan, 1990; Gambe & Getzel, 1989) may create a chronic lack of resources available to deal with stressors, thus compounding these adjustment problems. We now review some of these phenomena in greater detail to demonstrate how they interact.

8.10.2.3.1 Uncontrollable stressors

There are numerous psychosocial challenges following a diagnosis of HIV seropositivity. Among 240 gay and bisexual men, specific stressors—receiving an HIV-positive diagnosis, an AIDS diagnosis, an AIDS-related complex (ARC) diagnosis (the prior designation for having overt HIV-related symptoms but not yet developing AIDS), and learning of the death or AIDS diagnosis of a lover—were rated as the most emotionally distressing events that these people deal with (Rosser, Simon, & Michael, 1988). It is well-established that stressful life events shown to relate to depression and physical health consequences are those which are perceived as being beyond the individual's control (Justice, 1985). These events may also relate to increases in negative health behaviors. A variety of stressful events have been associated with alcohol consumption (Foy, Sipprelle, Rueger et al., 1984; Newcomb & Harlow, 1986) and low personal control is believed to be a mediator of this relationship (Beckman, 1980; Pearlin & Radabaugh, 1976). Similar findings are evident in gay men and may be more prevalent than in other populations given the reinforcement of heavy drinking in gay bars, a primary social gathering place (Nardi, 1982). Prevalence may similarly be enhanced in homosexual men as well as in ethnic minority group members due to the likelihood that alcohol (and drugs) are used to cope with burdens associated with being gay or otherwise disenfranchised in the society (e.g., guilt, anxiety, alienation, powerlessness) (Lohrenz et al., 1978). According to the identity disruption model (Lohrenz et al., 1978), negative life events that disturb one's self-concept or identity have the greatest deleterious effects. Self-conceptions determine the way personal information is appraised and processed, and the nature of social interactions. Identity disruptions, according to this model, may impair functioning by causing individuals to devote excess time and energy to the stressor, and undermine their sense of control and ability to predict other aspects of their lives. For those diagnosed with HIV infection, each HIV-associated stressor experienced may erode their previous self-concept giving way, possibly, to self-blame for their seropositivity (Hoffman, 1991).

8.10.2.3.2 Stressor appraisals

In addition to providing an overt sign of disease progression, physical changes such as skin lesions, muscle wasting, and fungal infections may compromise self-image in HIV-infected persons (Hoffman, 1991; Ostrow, Monjan et al., 1989). Infected individuals who see the onset of these changes as uncontrollable may attempt to cope by way of denial and increased substance use (Kaisen & Anton-Culver, 1989). These maladaptive strategies may affect psychological adjustment, future risk behaviors, and physical health (Burns et al., 1991; Ironson et al., 1992; Penkower et al., 1991). It is well known that a person's appraisal of stressful events may determine the individual's coping responses and emotional state (e.g., depression) (Lazarus & Folkman, 1984). Appraisals that are particularly relevant to the demands of an HIV diagnosis include those concerning harm/loss (e.g., loss of relationships, physical abilities, independence [Beckett & Rutan, 1990; Ferrara, 1984], threat (e.g., threat/anticipation of future symptoms [Hoffman, 1991]), and challenge (e.g., opportunities for personal growth)—three domains that have been studied extensively by Lazarus and Folkman. Thus, one important goal of psychosocial intervention is to help individuals enhance their sense of self-efficacy for dealing with the losses, threats, and challenges characterizing the physical and psychosocial sequelae of their HIV infection. Efforts to build self-efficacy may be most effective early in the course of the psychosocial intervention and can be enhanced by constructing a supportive group environment and teaching participants tangible strategies for managing daily hassles as well as major environmental stressors and their cognitive, behavioral, emotional, and interpersonal responses to these events.

8.10.2.3.3 Coping with HIV-related symptoms

Individuals previously diagnosed with HIV infection, who have not yet developed AIDS-defining symptoms, report an overwhelming sense of uncertainty (Dew et al., 1990). This uncertainty may actually contribute to the higher incidence of adjustment disorders reported for those with symptomatic pre-AIDS conditions vs. those with full-blown AIDS (Dilley et al., 1985). Uncertainty about one's immediate future creates critical demands for coping, the success of which may depend upon an individual's appraisals, attributions of blame, opportunities for social comparison, repertoire of adaptive coping strategies, and the sense of self-efficacy necessary for using these strategies.

Coping strategies classified as active-behavioral (planning, seeking social support) or active-cognitive (finding meaning in an illness, reframing) have been related to more positive affect and higher self-esteem in various chronic disease populations (Billings & Moos, 1981; Bloom, 1982; Fawzy et al., 1990; Felton, Revenson, & Hinrichsen, 1984). Conversely, denial and avoidance strategies are associated with greater depression and distress (Billings & Moos, 1981; Namir, Wolcott, Fawzy, & Alumbaugh, 1987). Individual differences in available coping strategies for dealing with stressors may be among the most significant predictors of depression and future adjustment to HIV seropositivity (Namir et al., 1987; Weimer, Nilsson-Schonnesson, & Clement, 1989) and may, possibly, play a role in future clinical disease progression (Ironson et al., 1992). One group prospectively related coping strategies and immunologic measures in HIV seropositive gay men over the one year period following notification of their antibody test results (Antoni et al., 1995a). Asymptomatic seropositive men's coping responses to antibody status notification were measured concurrently with phenotypic and functional immunologic markers, and these immunologic measures were taken again one year later. Seropositive men scoring above the median on postnotification disengagement coping strategies (denial, behavioral disengagement, mental disengagement) had significantly lower concurrently measured T-helper/suppressor (CD4/CD8) cell ratios, T-helper–inducer subset (CD4 + CD45RA +) % values, and proliferative responses to PHA than men scoring below the median on these scales. Disengagement coping responses also predicted one-year follow-up immune status; greater disengagement predicted poorer lymphocyte responsivity to PHA. Together these preliminary findings suggested that strategies that distract seropositive individuals from the stress of infectivity are related to greater levels of depressed affect and distress, as well as more impairment on some immunologic measures, and these relationships appeared to persist over as long as a 12-month period.

8.10.2.3.4 Social support

Social resources have been found to buffer the negative physical and psychological effects of major stressful events ranging from concentration camps to hurricanes (Lutgendorf et al., 1995; Sarason, Potter, Sarason, & Antoni, 1985; Schneiderman et al., 1992). Buffering effects of social support have been attributed to increased opportunities for intimacy, integration through shared concerns, reassurance of worth, nurturance, reliable alliance, and guidance—all potentially facilitating task-oriented thinking and active coping while decreasing helplessness and depression (Sarason, 1979). On the other hand, socially isolated individuals may be more likely to maintain maladaptive stressor appraisals such as catastrophizing, self-blame, and helplessness, and may employ denial as a chief coping strategy. The many losses in interpersonal and institutional support resources (Hoffman, 1991) may be responsible for the sense of isolation reported by some HIV-infected individuals (Dilley et al., 1985).

Issues regarding social support may be especially salient for HIV-infected women, many of whom are indigent minority group members who have been marginalized by their social groups leaving them with limited resources available to care for themselves or their children (Guinan, 1987; Nyamathi & Lewis, 1991). This threatens their roles as caregivers and mothers significantly (Buckingham & Rehm, 1987; Chung & Magraw, 1992). Trying to cope with being ill and the challenges of motherhood concurrently can be overwhelming. Having to disclose to children one's serostatus and medical condition are further challenges that these women face. Women with AIDS feel and experience stigma and shame by being presumed to be dangerous (Chung & Magraw, 1992). Community support efforts may appear to them to be primarily directed to gay men and they may respond to this with resentment and despair (Mackie, 1993).

It is important to remember, however, that gay men may also be at increased risk of social isolation. Given the number of HIV-infected gay men experiencing multiple bereavements (Martin, 1988), coupled with their reported low average support network size (comprised mainly of friends) (Namir, Alumbaugh, Fawzy, & Wolcott, 1989), any loss in such social support may be especially devastating. Other, less stable, social resources such as employment circles (Chung et al., 1989; Dilley, et al., 1985) may also be lost as the HIV infection progresses, with job loss having negative effects on both financial status, self-esteem, and emotional functioning.

In a recently published review, Zuckerman and Antoni (1995) suggest that certain social support criteria are related to optimal psychological adjustment in HIV-positive individuals. These include:

(i) a general sense of feeling supported (Namir et al., 1989);

(ii) satisfaction with received support (Hays, Turner, & Coates, 1992);

(iii) perceived helpfulness of peers (Hays, Chauncey, & Tobey, 1990);

(iv) total perceived availability of support as well as individual dimensions of support (O'Brien, Wortman, Kessler, & Joseph, 1990; Turner, Hays, & Coates, 1993; Zich & Temoshok, 1987);

(v) absence of social conflict (Lesserman et al. 1995; O'Brien et al., 1993);

(vi) greater involvement in AIDS-related community activities (Lesserman, Perkins, & Evans, 1992); and

(vii) a greater number of close friends (Hays et al., 1990).

Each of these aspects of support has been associated with lower levels of depression and, in some studies, with lower levels of hopelessness, anxiety, mood disturbance, risk behaviors, and greater overall sense of psychological well-being in a variety of populations (Christ & Wiener, 1985; Cutrona & Russell, 1987; Donlou, Wolcott, Gottlieb, & Landsverk, 1985; Friedman et al., 1991; Namir et al., 1989; Ostrow, Joseph et al., 1989; Zich & Temoshok, 1987). One study found that greater support satisfaction and greater involvement in AIDS-related community activities were associated with a greater use of coping strategies such as cognitive reframing and fighting spirit which were in turn associated with less dysphoria and greater self-esteem (Lesserman et al., 1992). Prior studies of HIV-positive men suggest that social support may determine the choice between active behavioral coping and less adaptive strategies. For instance, greater social support availability and satisfaction associated with active coping and lower support availability is associated with a greater use of denial/avoidance strategies (Martin, 1989). Also, lack of family support and other important support sources have been proposed as contributors to alcohol abuse (Nardi, 1982), though little is known about the ways in which ethnicity and socioeconomic status may moderate this relationship. In a large cohort of gay men in San Francisco, men who reported always using condoms had higher levels of social support from informal sources of help (friends, sex partners) (Catania et al., 1991). Thus social support may be viewed as a coping resource to the extent that it channels, facilitates, or perpetuates the use of coping strategies with stress-buffering properties.

Unfortunately, social support may actually decrease as the number of symptoms increases in HIV-infected individuals (Hays et. al., 1990). This may be due to caregivers and other support network members pulling back from persons with AIDS (PWA) to prevent burnout and emotional exhaustion (Turner et. al., 1993). Since family members may attempt to distance themselves emotionally from this traumatic situation, the importance of peers and fellow PWA's in the social support networks of HIV-infected individuals may increase. These people can be important sources of informational support and often provide the greatest opportunity for support (Hays et al., 1990). As such, peers often fill in the "support gaps" left behind by family and professional caregivers (Zuckerman & Antoni, 1995).

It is important to realize that some forms of social interaction may actually be associated with increased levels of psychological distress in HIV-infected persons. Among asymptomatic HIV-infected gay men, increases in social conflict, and dissatisfaction with social support in general predicted greater increases in distress and depression over a one-year period (Lesserman et al., 1995). These social conflicts can include rejection messages from family members, breaking up or declining quality of romantic relationships, and trouble with employers, among others. Another study revealed that the type of support deemed most useful depended largely on the situation confronting the individual and the context of the support provision: emotional support was generally seen as being helpful from all providers in almost any situation, while informational or problem-solving support was viewed as helpful only from medical experts and other PWA's (Zich & Temoshok, 1987). The relative effectiveness of problem-focused vs. emotional-focused support may also depend on factors such as disease stage (asymptomatic vs. AIDS) and stressor qualities such as controllability. Folkman and colleagues have suggested that problem-focused coping strategies may be most useful when directed toward controllable aspects of stressors, while emotion-focused strategies may be most effective when targeted toward uncontrollable aspects of stressors (Folkman et al., 1991). Extending the coping theory of Folkman and her colleagues to the context of matching social support resources (e.g., emotional vs. informational) to situational demands (e.g., uncontrollable vs. controllable) has been proposed as a reasonable strategy for providing the most useful support to individuals who are dealing with the different burdens of HIV infection (Zuckerman & Antoni, 1995).

In sum, inadequate social support or a sense of social isolation may exaggerate the deleterious effects of stressful events on depression and negative health behaviors in HIV-infected persons (Cutrona & Russell, 1987). A seropositive diagnosis may reduce both the availability and utilization of social support (Christ & Wiener, 1975; Donlou et al., 1985) which may increase the risk of depression, hopelessness, and less adaptive strategies such as substance use (Friedman et al., 1991; Nardi, 1982; Ostrow, Joseph et al., 1989). Similar phenomena may occur in those diagnosed with HIV symptoms or full-blown AIDS for the first time (Namir et al., 1989; Zich & Temoshok, 1987). Thus social support may be related to depression, substance use, and sexual risk behaviors at many stages HIV infection. Its influence may also vary as a function of ethnicity, among other factors such as SES and educational level. While available and adequate social supports might enhance HIV-infected people's ability to manage their infection and related stressors by functioning as a key coping resource, negative conflictual social interactions may actually act as a deterrent to successful adjustment.

8.10.3 PREDICTING THE HEALTH COURSE OF HIV INFECTION

With the emergence of data in the 1990s from long-term cohort studies, it is now well-established that some patients who are HIV positive develop symptoms rapidly while others remain free of AIDS symptoms over a decade. From a secondary prevention standpoint this means that it is important to isolate factors that account for the wide variability in the transit time for the clinical manifestations of HIV infection. Since 1990, new terms have been developed to reflect those who somehow outlive or outpace their prognosis following HIV infection. One grouping consists of nonprogressors with HIV—persons who are HIV-positive yet maintain near normal levels of CD4 numbers. Another grouping consists of those who are asymptomatic low CD4—people with very low CD4 counts ($< 50\,\text{cells}\,\text{mm}^{-3}$) who remain asymptomatic for extended periods of time. Finally, there are those termed long-term survivors of symptomatic AIDS. While the sources of individual variability in HIV progression remain largely unknown, a growing body of literature suggests that the key may lie in some combination of biological and psychological factors (Ironson et al., 1995).

8.10.3.1 Biological Factors and Disease Progression

8.10.3.1.1 Constitutional factors

Some biological factors influencing length of survival (Friedland et al., 1991; Hardy et al., 1991) include age (e.g., younger persons live more years once infected [Jacobson et al., 1991; Lemp et al., 1990]), gender (e.g., men live longer following diagnosis with AIDS [Brown, 1989]), ethnicity, and initial AIDS-related disease manifestation (having Kaposi's sarcoma vs. PCP as the presenting symptomatic criterion for AIDS (Friedland et al., 1991). Risk group membership (Detels et al., 1988; Shine et al., 1987) and presence of, or prior history of, other concomitant sexually transmitted diseases (STDs) also appear important. Disease progression markers, such as CD4 cell counts, may also be predictive of disease progression. For instance, prior rate of CD4 decline and body mass index predict the amount of time until the infected people's level of CD4 cells drops below 200 cells mm^{-3}, the point at which symptomatic AIDS often occurs (Hoover et al., 1995).

8.10.3.1.2 Other viral infections

Another set of biological factors influencing the course of HIV infection may be the degree to which other latent viruses (e.g., several types of herpes viruses) become reactivated (Rosenberg & Fauci, 1991). This point, taken in view of the psychosocial phenomena reviewed previously, is a critically important consideration for PNI research with HIV-infected populations given that (i) several psychosocial stressors have been related to immune system decrements and to signs of reactivation of one or more latent herpes viruses, and (ii) increases in sexual risk behaviors, which may ensue following some of these psychosocial phenomena, may place infected individuals at greater risk of contracting a new herpes virus infection. It has been reasoned that if stressors (Glaser & Kiecolt-Glaser, 1987) and behavioral interventions (Antoni, Esterling, Lutgendorf et al., 1995) affect the immune system's ability to control latent herpes viruses in a wide variety of populations, then stressors and interventions might also influence herpes virus-mediated progression of clinical disease in HIV-infected individuals.

Importantly, herpes viruses persist in the host indefinitely once they are infected (Rinaldo, 1990). Varicella and HSV establish latent infections in neurons, whereas CMV, Human Herpes Virus Type-6 (HHV-6), and EBV persist in lymphocytes. When an individual is infected with one of the herpes viruses, seroconversion and latency results, with or without the presence of clinical disease. In healthy individuals, herpes viruses can reactivate spontaneously and often in the absence of clinical symptoms. Under sustained states of cellular immunodeficiency, such as in persons infected with HIV or in those undergoing immunosuppressive therapy for renal transplant, reactivation of one or more of the latent herpes viruses results in severe morbidity (Ernberg, 1986; McVoy & Adler, 1989; Rinaldo, 1990; Yao, Rickinson, Gaston, & Epstein, 1985). Moreover, herpes viruses are known to suppress a wide number of immunologic functions including cytokine production and lymphocyte blastogenesis to mitogens (Rinaldo, 1990). These phenomena suggest that HIV and herpes viruses may interact to perpetuate disruptions in the biological control of each respective infection, possibly contributing to the severity and chronicity of related clinical signs and symptoms.

Because several herpes viruses prevalent in HIV-infected individuals are known to have independent immunosuppressive effects, reactivation of these viruses could have implications for progression to AIDS (Griffiths & Grundy, 1987). Subclinically these surveillance effects may be observed as rising antibody (IgG) titers to EBV, HHV-6, CMV, and HSV-2. One could speculate that clinically, the inability to survey these latent viruses may be manifest in EBV-associated Burkitt's lymphoma (Doll & List, 1982) and oral hairy leukoplakia (Eversole, Stone, & Beckman 1988; Greenspan et al., 1985); CMV-associated retinitis, encephalitis hepatitis, adrenalitis, and gastrointestinal pathologies (Blumberg, 1984; Henderly et al., 1987; Schooley, 1990; Tapper et al., 1984); and HSV-associated proctitis (Goodell et al., 1983), esophagitis (Levine, Woldenberg, Herlinger, & Laufer, 1987), and aseptic meningitis (Dahan, Haettich, LeParc, & Paolaggi, 1987).

There is also evidence that reactivation of several of these herpes viruses may act to further stimulate HIV replication and progression to AIDS (Carbonari et al., 1989; Hammarskjold & Heimer, 1988; Lusso et al., 1989; Rosenberg & Fauci, 1991; Sumaya, Boswell, & Ench, 1986). CMV, one of the herpes viruses, is an important opportunistic pathogen in HIV infection (Rinaldo, 1990) and has been shown to enhance susceptibility to secondary opportunistic pathogens in immunosuppressed populations (Perssan et al., 1987). It is among the most immunosuppressive of the herpes viruses impairing blastogenic responses and γ-interferon production by T-lymphocytes (Rinaldo, 1990) and it has also been shown to alter the growth and expression of HIV in culture, possibly accelerating progression to AIDS among infected persons (Biegalke & Geballe, 1991; Paya, Virelizier, & Michelson, 1991). Webster (1991) found that among HIV-infected individuals, the age-adjusted relative risk of developing AIDS was 2.5 times higher in those who were coinfected with CMV compared to those who were CMV seronegative.

In sum, although some mechanisms are still being explored, the fact that herpes viruses may be related to HIV associated sequelae is intriguing. For example, because HHV-6 may reactivate during EBV infections, and because both EBV and HHV-6 may reactivate following immunosuppression by HIV, these three viruses may potentiate one another in the progression of clinical disease. Through direct immunosuppression or transactivation of HIV (by CMV or HSV), latent herpes viruses may be considered as potential cofactors in the development of AIDS. It is quite plausible that HIV-associated effects on the cells of the immune system may perpetuate a downward spiral in the functional ability of the immune system to survey and control latent viruses which, when left unchecked, may act to increase replication of the primary virus.

The implication of these findings is that the host's ability to control such viruses may be a "downstream" immune system marker that has more meaning as a predictor of HIV clinical disease and possibly the acceleration of viral load than does the CD4 cell count alone. We know that changes in HIV viral load, viral character (appearance of syncytium-inducing variants), and CD8-directed cytotoxity against HIV are the key predictors of individual differences in clinical disease progression (Pantaleo et al., 1993). These "predictors" all speak to the importance of the host maintaining vigorous surveillance and control over HIV (through well-coordinated cytotoxic responses), and stabilized HIV replication (reflected in stable viral load and predominantly nonsyncytium-producing types). Given this understanding of the importance of qualitative aspects of the immune system (surveillance functions and signs of poorly surveyed viruses) in HIV disease progression, it is surprising that so little research has been published on the effects of biomedical and psychosocial interventions on qualitative immune measures including those reflecting surveillance of specific pathogens such as latent herpes viruses.

8.10.3.2 Behavioral and Psychosocial Factors and Disease Progression

8.10.3.2.1 Behavioral factors

Behavioral factors such as the use of alcohol, tobacco, caffeine, recreational drugs (cocaine, nitrites) during sex, unprotected anal intercourse, and poor nutrition have also been suggested as possible cofactors of accelerated HIV disease progression (Chiappelli, Ben-Eliyahu, Hanson & Wylie 1992; Griensven et al., 1990; Haverkos, Pinsky, Drotman, & Bregman, 1985). It is noteworthy that several of these behaviors have been associated with immunomodulation in other populations. Cigarette smoking has been associated with significant decreases in helper cells and increases in suppressor/cytotoxic cells (Miller, Goldstein, & Murphy, 1982). Alcohol use has been related to depressed cell-mediated immunity (Watson, Eskelson, & Hartman, 1984), decreased lymphocyte number and diminished lymphocyte blastogenesis (Glassman, Bennet, & Randal, 1985), bone marrow myelosuppression (Tisman et al., 1971), and abnormal granulocyte chemotaxis (Atkinson et al., 1977). Other work suggests that alcohol abuse may amplify the suppressive effects of mental depression on immunologic impairments (Irwin, Caldwell et al., 1990). Recreational drug usage (e.g., heroine) has been associated with depressed cellular immune functioning in one study (Lazzarin, Mella, & Trombini, 1984), and with suppressed NK cell killing in another (Katz, Zaytoun, & Faici, 1982). Some of this work has focused specifically on HIV-infected samples. For instance, there is growing evidence that injection drug use (Seage et al., 1993; Weber, Ledergerber, Opravil, Siegenthaler & Luthy, 1990) and even cigarette smoking (Burns et al., 1991; Nieman, Fleming, Coker, Harris, & Mitchell, 1993; Royce & Winkelstein, 1990) may be associated with faster disease progression in HIV-infected people. The specific mechanisms by which these substances affect immune functioning are still in the process of being elucidated. It is noteworthy that some of these substances are associated with alterations in those physiological stress response systems noted previously. For instance, nicotine in cigarette smoke is associated with catecholamine discharge (Blaney, 1985) and ethanol consumption is also linked with catecholamine elevations due to blockage of re-uptake (Davidson, 1985).

Nutritional factors and vitamin deficiencies may contribute to immunologic decrements in HIV infection. Protein-caloric malnutrition is associated with a wide range of immune impairments and is believed to explain the increased susceptibility to disease in undernourished populations of many Third World countries (Stites, Stobo, Fudenberg, & Wells, 1982). Some work also suggests that alterations in certain vitamin levels, for instance, vitamin B^6 deficiencies, may be associated with immune system decrements in HIV-infected persons (Baum et al., 1991).

A series of studies has presented evidence for immunomodulatory effects of sleep deprivation including decreases in lymphoproliferative responses and diminished granulocyte functioning (Palmblad et al., 1976; Palmblad, Petrini, Wasserman, & Akerstedt, 1979). One study, done in the mid-1990s, noted that the decrements in immune function (NKCC) evident in victims of a hurricane over the months following the storm were mediated, in part, by sleep disruptions (Ironson et al., 1997). Other work has indicated that human IL-1 levels peak at the onset of slow wave sleep (Krueger & Karnovsky, 1987), suggesting that cellular immunity may be affected by qualitative, as well as quantitative, aspects of sleep and accompanying cytokine changes. Important for HIV-infected populations is the fact that sleep disruptions are one of the hallmarks of clinical depression.

Numerous other biological factors may alter stress hormone levels and immune functioning such as aging, steroid use, sex hormone fluctuations, radiation treatment, as well as a multitude of medication regimens (Stites et al., 1982). Generally these variables are not likely to be responsive to health psychology interventions and thus will not be reviewed here. However, it is essential that these phenomena and others be measured and carefully controlled in any investigations of the influence of biological, behavioral, and psychosocial factors in HIV disease progression.

Another variable that may deserve further attention is heightened sympathetic nervous system responsiveness to stressful situations. The stress hormonal elevations known to accompany this hyper-responsiveness (Rose, 1980) may have immunomodulatory effects. Interestingly, a growing literature suggests that pharmacologic agents that attenuate cardiovascular hyper-responsiveness (Bonelli, 1982; Dimsdale, Hartley, Ruskin, Greenblatt, & Labrie, 1984) may also alter immune functioning (Benschop et al., 1994; Hatfield, Petersen, & DiMicco, 1986; Weisdorf & Jacob, 1987). There is also some evidence that HIV-infected persons may display altered cardiovascular, endocrine, and immunologic reactivity to laboratory stressors (Kumar, Morgan, Szapocznik, & Eisdorfer 1991; Starr et al., 1996), indicating that these individuals may not respond to and recover from stressful challenges in the same way that healthy, uninfected people do.

Although there is little known about the direct immunomodulatory effects of different forms of sexual behaviors, it is plausible that repeated exposure to novel strains of HIV and other sexually transmitted pathogens by way of unprotected intercourse (e.g., HSV and human papilloma viruses [HPVs], may contribute directly to the development of opportunistic infections (e.g., systemic HSV-2 infections) and neoplasias (e.g., HPV-associated cervical and anal intraepithelial neoplasias [Antoni & Goodkin, 1996]). In addition, exposure to these pathogens may indirectly contribute to an accelerated disease course by promoting HIV replication (for review see Antoni, Esterling, Lutgendorf et al., 1995). Therefore, efforts to modify risky sexual behaviors in already infected individuals can be seen as a secondary prevention strategy. Finally, PCP treatment prophylaxis, antiretroviral combination therapy, and the new breed of protease inhibitors may influence survival after AIDS onset (Saah et al., 1994). From a behavioral standpoint, an HIV-infected individual's decision and actions taken to pursue these treatments, at the earliest point following the emergence of symptoms or after dropping below landmark values for CD4 cell counts (e.g., $< 200\,\text{cell mm}^{-3}$), may play a large role in health maintenance.

We have reasoned that if psychological factors affect the immune systems of HIV-infected individuals, then even small immune changes might have clinical relevance since this population's immunologic functioning is already significantly impaired by the virus (Antoni, Schneiderman et al., 1990; Schneiderman et al., 1994). Healthy uninfected people in the normal population possess many checks, balances, and compensatory mechanisms built into their immune systems. Since HIV-infected individuals are just at, or above, the number of T-lymphocyte subsets necessary for responding to encountered pathogens (e.g., 200–500 CD4 cells mm^{-3}), then small changes, of unknown magnitude, could quite possibly have an impact on the incidence of a wide range of infections due to normally harmless bacterias, viruses, fungi, and other opportunistic pathogens.

In addition to behavioral factors, there is some evidence that several psychosocial variables may also contribute to individual differences in disease progression among asymptomatic HIV-infected individuals as well as contributing to differences in survival time in those who have already developed AIDS. Specifically, longitudinal studies have identified psychological factors such as depressive symptoms, stressful life events, maladaptive coping strategies, and social isolation that predict either survival time or CD4 changes over a period of years.

8.10.3.2.2 Depressive symptoms

There is considerable evidence that depressive symptoms are correlated with immunosuppression in otherwise healthy individuals (Herbert & Cohen, 1993; Irwin, Caldwell et al., 1990; Irwin, Patterson et al., 1990), though available evidence suggests that depression and affective disturbances may be associated with physical disorders in a bidirectional fashion (Cohen & Rodriquez, 1995). Much of the work relating clinical depression and depressed affect to immunologic changes is plagued with inconsistencies which may be attributable, in part, to the use of small samples, variability in control/comparison groups utilized, and variance in the depression diagnostic criteria employed (Stein et al., 1991). However, alterations in NKCC appear to be the most commonly observed immunologic correlate of depressed affect and depressive disorder employed (Stein et al., 1991). Among the more recent and well-controlled studies, Irwin, Caldwell et al. (1990) found significant NKCC decrements associated with depressive disorders.

Longitudinal studies relating depressive symptoms to rates of immunologic decline and disease progression in HIV-infected persons have produced mixed results (Burack et al., 1993; Lyketsos et al., 1993; Patterson et al., 1996). Burack and colleagues found that greater depressive symptoms predicted a faster decline in CD4 counts but were not associated with time to AIDS or survival time in early-stage HIV-infected gay men followed over a six-year period (Burack et al., 1993). Lyketsos used similar criteria for documenting the presence of depressive symptoms and found no prospective relationship with either CD4 count slopes of decline or clinical disease progression over a similar period (Lyketsos et al., 1993). However, there was a tendency for the men in the Lyketsos study to be at a more advanced stage of CD4 cell loss at start of the study than those men in the Burack study. Another study following HIV-infected men over a five year period observed that depressive symptoms predicted shorter survival time after controlling for initial symptoms and CD4 cell number (Patterson et al., 1996). Other psychosocial factors may interact with depressive symptoms or distress levels in predicting changes in immune status and health. Because depressed affect, substance use, and risky sexual behaviors may all contribute to health outcomes in HIV-infected individuals, it seems reasonable that factors which moderate the occurrence of these sequelae may also have an influence on immunity and health. Some of these include the occurrence of overwhelming stressful life events, stressor appraisals, individual differences in coping skills, and differences in social support.

8.10.3.2.3 Stressful life events

There is now ample literature (Herbert & Cohen, 1993) showing that stressors are associated with decrements in immune function. Some of these stressors may be particularly prevalent among HIV-infected people attempting to cope with their illness and include: bereavement (Bartrop, Lazarus, Luckhurst, Kiloh, & Penny, 1977; Irwin, Daniels, Bloom et al., 1987; Kemeny et al., 1995; Linn, Linn, & Jensen, 1981); unemployment (Arnetz et al., 1984); the stress of being a caregiver for a loved one with a terminal disease (Kiecolt-Glaser, Glaser et al., 1987; Kiecolt-Glaser et al., 1991); divorce (break-up) (Kiecolt-Glaser, Fisher et al., 1987); and marital distress (Kiecolt-Glaser, Fisher et al., 1987; Kiecolt-Glaser et al., 1988). Chronic uncontrollable stress has been operationalized in one form as people dealing with catastrophic environmental changes. These stressors are also associated with immune alteration—for instance, both at the Three Mile Island nuclear plant disaster (McKinnon, Weisse, Reynolds, Bowles, & Baum, 1989) and in Miami after Hurricane Andrew (Ironson et al., 1997; Lutgendorf et al., 1995).

Recently conducted investigations indicate that the most consistent immune decrements found in studies of stressors are functional measures associated with cellular immunity (Bartrop et al., 1977; Glaser, Rice, Speicher, Stout, & Kiecolt-Glaser, 1986; Glaser, Kiecolt-Glaser, Speicher, & Holliday, 1985; Glaser et al., 1987, 1990, 1991; Ironson et al., 1995; Irwin et al., 1990; Kemeny et al., 1995; Kiecolt-Glaser et al., 1985, 1987, 1988; Kiecolt-Glaser, Dura, Speicher, Trask, & Glaser, 1991; Levy, Herberman, Lippman, d'Angelo, 1987; Linn et al., 1981). These include, but are not limited to:

(i) decrements in blastogenic responses to phytohemaglutinin (PHA) and pokeweed mitogen (PWM);

(ii) decreased natural killer cell cytotoxicity (NKCC);

(iii) increased antibody titers to Epstein-Barr Virus (EBV) and Herpes Simplex Viruses (HSV);

(iv) poorer DNA repair; and

(v) disturbance in cytokine regulation including less γ-interferon and interleukin-2 (IL-2) production and IL-2 receptor gene expression.

There are some PNI studies that have related stress responses to people's ability to respond to viral pathogens. Cohen and colleagues (Cohen, Tyrrell, & Smith, 1991) innoculated volunteers with one of five rhinoviruses (cold viruses) in a restricted environment and then followed them over a period of weeks. Subjects with the highest levels of perceived stress were significantly more likely to display increases in antibody titers to the specific rhinovirus and clinical colds than those with the lowest levels of psychological stress. Stressors have also been related to alterations in primary immune responses to other viruses. Glaser et al. (1992) demonstrated that those medical students undergoing a stressor (exams) who were least stressed and anxious were also the most likely to seroconvert (produce a primary antibody response to) the Hepatitis B virus (HBV) after the first vaccine innoculation. In addition, participants with the highest levels of social support had a stronger immune response to the vaccine at the third innoculation. Thus, participants with low stress and anxiety, and high social support, appear to have been relatively well protected from infection by HBV. Together these studies suggest that stressors may influence mechanisms controlling both primary and secondary immune responses to viruses. This work is important for understanding the role of stressor–immune associations as they possibly relate to health outcomes in the context of HIV infection since an HIV-infected person's inability to control viral co-infections may act to aggravate the course of primary HIV infection (Antoni et al., 1995).

Despite some of the evidence associating stressful life events with changes in specific indices of immune system functioning in healthy populations that has accrued since the mid-1980s, there is less conclusive evidence linking stressors with immune and health changes in HIV-infected individuals. Briefly, two studies found that stressful life events were unrelated to CD4 counts or HIV-related symptoms (Kessler et al., 1991; Rabkin et al., 1991), while another found that elevated life events were predictive of decreases in CD4 counts (Goodkin, Fuchs, Feaster, Leeka, & Rishel, 1992). It should be noted that Goodkin and colleagues analyzed their data in line with a stressor–moderator model which simultaneously takes into account the direct effects of life events, plus their interaction with theoretically derived moderator variables such as coping and social support. Such more sophisticated statistical modeling may be necessary to delineate the often interactive nature of life event effects on the immune system and health.

One stressful event associated with disease progression in HIV-infected persons is bereavement (Coates, Stall et al., 1989; Kemeny et al., 1994). Coates, Stall et al. (1989) found that both the number of losses and accompanying distress levels were significantly related to faster HIV progression during a two-year follow-up. Similarly, Kemeny et al. (1994) found that a bereaved group of HIV-infected men who had lost a partner had significantly higher serum neopterin levels and lower proliferative responses to PHA than a matched group of nonbereaved HIV-positive men. This suggests that life events that are commonly experienced by HIV-infected individuals may have significant effects on the functioning of their immune system, but that gross changes in CD4 counts and clinical symptoms may take longer to develop. While the Rabkin et al. (1991) and Kessler et al. (1991) studies found no association between stressful life events and outcome measures, they did not assess individual differences in subjects" perceived control over stressful life events nor their coping responses for dealing with these stressors. While other life events have been associated with some immune measures in HIV-infected people (Evans, Pettito, & Leserman, 1992; Goodkin et al., 1992), stressful life events per se have not been shown to be predictive of a faster rate of disease progression (Kessler et al., 1991). Patterson and colleagues note that the interaction between mounting life events and distress levels may be a more reliable predictor of immunologic and health changes in HIV-infected persons (Patterson et al., 1996). Specifically, individuals who display the greatest distress levels during particularly stressful periods may show the poorest health outcomes. It is plausible that those individuals who are at greater risk of displaying such distress levels are those who utilize maladaptive stressor appraisals and coping strategies and who also have inadequate social resources.

8.10.3.2.4 Stressor appraisals

Some aspects underlying the cognitive processing of stressors have been associated with measures of physiological activation and immune functioning in healthy people. Davidson and Baum (1986) found that both intrusive imagery and avoidant cognitions, as measured by the Impact of Event Scale (IES) (Horowitz, Wilner, & Alvarez, 1979), were positively associated with increased cortisol levels in residents living near Three Mile Island (TMI) following the nuclear reactor accident. Many of these individuals displayed elevated antibody titers to certain viruses, suggesting impairments in immunologic surveillance years after the reactor accident (McKinnon et al., 1989). Workman and LaVia (1987) found that intrusive cognitions (measured by the IES) related to an impending medical school examination were associated with poorer blastogenic responses to PHA among young healthy medical students. Ironson and colleagues found that the intrusive thoughts and post-traumatic stress symptoms experienced by many victims of Hurricane Andrew were associated with decrements in NKCC (Ironson et al., 1997).

One study examined how the manner in which HIV-infected individuals processed the stress of seropositivity notification predicted their immunologic status during the early period of adjustment to this stressor. They found that changes in style of cognitive processing of this stressor were significantly correlated with changes in affective and immunological functioning over this 10 week period (Lutgendorf, Antoni, Ironson, Schneiderman et al., 1997). The IES and the Profile of Mood States (POMS) (McNair, Lorr, & Droppleman, 1981) were administered five weeks before (baseline) and five weeks after notification (week 10). A panel of immune assays were also conducted on blood samples collected at these time points. The IES instructions required subjects to report on intrusive thoughts that they had been experiencing in the past week regarding one of the most salient issues that infected people deal with on a daily basis: the threat of AIDS in their life. The IES also tapped the degree to which they had attempted to distract themselves or avoid thinking about this threat over this period. Participants were classified as those who had IES-Intrusion score increases vs. decreases and those who had IES-Avoidance score increases vs. decreases over the 10-week period. Results indicated that men with avoidance increases demonstrated greater anxiety, depression, and confusion at week 10 than those individuals who had avoidance decreases. Subjects with avoidance increases also displayed lower proliferative responses to PWM and lower NKCC at the end of the 10 weeks compared to those who decreased in avoidance scores over the study. These findings suggested that postnotification processing, colored by avoidance, was associated with poorer immune system functioning in the weeks after antibody testing among asymptomatic HIV-positive men.

Another stressor appraisal variable that has received some attention in HIV research concerns a construct called fatalism. In a series of studies, Kemeny (reviewed in Kemeny, 1994) found fatalistic appraisals to be related to poorer health outcomes in HIV-infected gay men. In the first study, fatalistic gay men with a diagnosis of AIDS had a significantly shorter survival time than men scoring low on fatalism (Reed, Kemeny, Taylor, Visscher et al., 1994). Interestingly, men who were both fatalistic and bereaved within the past year had the shortest survival time (Reed, Kemeny, Taylor, Visscher et al., 1994), the steepest declines in CD4 number and proliferative response to PHA, and a more rapid increase in disease progression markers, including neopterin and beta-2 microglobulin (Kemeny et al., 1995). Less is known about the ways in which other cognitive appraisal variables, such as optimism, different cognitive distortions, such as catastrophizing, and self-efficacy might relate to the course of HIV infection.

8.10.3.2.5 Coping strategies

There is some evidence that the use of certain coping strategies for dealing with HIV infection may be associated with the rate of disease progression. Ironson et al. (1994) found that the use of denial and behavioral disengagement to cope with an HIV-positive diagnosis, was predictive of lower CD4 counts at 1 year follow-up (controlling for CD4 counts at entry to the study) and greater likelihood of progression to HIV-related symptoms and AIDS at 2-year follow-up. A more fine-grained analysis exploring the immunologic changes that occurred in this sample prospectively related coping strategies and immunologic measures in the HIV seropositive gay men (and a seronegative comparison group of gay men) over the 3 week and 1-year period following notification of their antibody test results (Antoni et al., 1995). Seropositive men scoring above the median on postnotification disengagement coping strategies (denial, behavioral disengagement, mental disengagement) had significantly lower concurrently measured T-helper/suppressor (CD4/CD8) cell ratios, T-inducer subset (CD4 + CD45RA +) percent values, and proliferative responses to PHA than subjects scoring below the median on these coping scales. Greater disengagement coping responses also predicted poorer lymphocyte responsivity to PHA at 1-year follow-up.

Consistent with these findings, Goodkin et al. (1993) found that use of passive coping strategies (including denial and disengagement) was inversely related to long-term CD4 cell count in HIV-positive gay men. Solano et al. (1993) also found that denial/repression was associated prospectively with the emergence of symptoms in an HIV-positive sample. Mulder, Antoni, Duivenvoorden et al. (1995) found that active confrontational coping with HIV infection was predictive of decreased clinical progression over a 1-year period after taking into account baseline biomedical and behavioral variables. Finally, Blomkvist et al. (1994) followed HIV-infected hemophiliacs longitudinally and found that self-oriented active-optimistic coping behavior was related to prolonged survival after controlling for age and CD4 counts at study entry. Thus, there is some evidence that coping strategies may be reliably associated with certain immunologic and health measures in HIV-infected persons from a variety of risk groups.

It should be noted that while Reed, Kemeny, Taylor, Wang, & Visscher (1994) found that realistic acceptance was a significant predictor of decreased survival time in gay men diagnosed with AIDS, Ironson et al. (1994) observed that greater use of denial among asymptomatic HIV-infected gay men predicted a greater likelihood of developing symptoms or AIDS two years later. Thus it appears that being at the extreme end of either denial or realistic acceptance might be dysfunctional. Kemeny refers to the realistic acceptance factor as fatalism–acceptance, and notes, specifically, that "fatalistic men survived a significantly shorter period of time when compared to their less fatalistic counterparts." What is not clear is whether this variable represents acceptance as a healthy coping style or a predominantly negative view (pessimism) about the future. One study may shed some light on the notion of a balance between the extremes of denial and acceptance. Mulder et al. (in press) found that greater use of distraction (e.g., focusing on other things to take the mind off things) predicted a slower rate of decline in CD4 cells, less appearance of syncytium-inducing HIV variants, and less progression to immunologically defined AIDS (< 200 CD4 cells mm^{-3}) over a 7-year period. Ironson et al. (1995) notes that together these findings suggest that strategies which are predictive of longevity may involve using some distraction coupled with staying away from the extremes of either denial or acceptance to the point where fatalism and rumination occurs.

8.10.3.2.6 Social support

The health promoting effects of social support that have been most widely researched are usually in terms of its ability to buffer the effects of stressors (Cohen & Wills, 1985). A person's social support network may also influence their ability to manage, cope with, and recover from serious illness (Dimatteo & Hays, 1981; Taylor, Falke, Shoptaw, & Lichtman, 1986; Wortman & Conway, 1985). Since the 1970s there has been an enormous amount of research undertaken studying the ability of social networks to provide positive physical health benefits to people (Berkman & Syme, 1979; House, Landis & Umberson, 1988; Smith, Fernegel, Holcroft, Gerald, & Marien, 1994; Wortman & Dunkel-Schetter, 1987). Some findings have converged across investigations. For instance, it appears that being involved in a committed relationship (i.e., marriage) is associated with greater survival time among patients who have experienced a myocardial infarction (Wiklund et al., 1988; Williams et al., 1992) or a diagnosis of breast cancer (Neale, Tilley, & Vernon, 1986). However, these associations have not been replicated in other studies. Although a growing body of evidence supports the potential benefits of social ties in healthy people and several chronic disease populations (e.g., cancer patients), scientists are just beginning to examine the health correlates of social support in HIV-infected individuals.

A variety of models have been developed to explain the ways in which social support might provide direct influences on psychological and physical well-being (Cohen & Wills, 1985). Some of these direct psychological benefits may stem from the possibilities that social support helps people define certain stressors as being less overwhelming, provides opportunities for people to openly express fears, frustrations, and other emotions, thereby decreasing ruminations and obsessive thinking about stressors. Social support also provides key information and informational support provided by knowledgeable others, which may help individuals to assume a more realistic attitude toward life goals. In addition, social support may help people feel connected, which may increase their sense of self-worth, belongingness, meaning, purpose, and well-being. Finally, social ties may reduce initial feelings of burden caused by the onset of a stressor (e.g., a medical diagnosis), allowing the person to employ active coping strategies to deal with the stressor. Obviously, all of these benefits of social support may be highly salient for HIV-infected persons (Zuckerman & Antoni, 1995).

Some research suggests that the same mechanisms which provide these psychological benefits from social support also seem to buffer endocrine and immunologic changes associated with stress responses (e.g., Baron, Cutrona, Hicklin, Russell, & Lubaroff 1990; Cobb, 1974; Esterling, Kiecolt-Glaser, & Glaser, 1996; Levy et al., 1987). It has been hypothesized that HIV-infected people who maintain strong support networks may have less extreme and protracted biological responses to stressors because SAM and HPA-related stress hormone levels (e.g., peripheral catecholamines and cortisol) are better regulated (Antoni et al., 1990). Some work provides preliminary evidence that social support may relate to the rate of HIV disease progression as well. One study found that larger social network size and greater perceived informational social support predicted greater survival time in HIV-infected men, but only among those with AIDS symptoms (Patterson et al., 1996). Other prospective studies have found that greater social support availability (Theorell et al., 1995) and more frequent use of problem-focused support (Solomon, Temoshok, O'Leary, & Zich, 1987) were predictive of a slower decline in CD4 counts and longer survival, respectively. Another study may illuminate a factor underlying an HIV-infected person's decision to enlist social support. Cole, Kemeny, Taylor, Visscher, and Fahey (1996) followed 80 HIV seropositive (non-AIDS, normal levels of CD4 lymphocytes at entry) gay men for 9 years and found that those who concealed their sexual identity (being at least "half in the closet") had a faster decline in CD4 counts, shorter time to AIDS diagnosis, and shorter time to AIDS mortality than those who did not conceal their identity. Therefore, social support availability, decisions to utilize available support, and identity factors that influence decisions to make these connections may all contribute to the course of HIV disease.

In sum, it could be hypothesized that a mounting number of losses and grieving experiences, which constitute prevalent life stressors for HIV-infected individuals, might contribute to a faster rate of disease progression. Further work suggests that maintaining fatalistic stressor appraisals could predict shorter survival time among men with AIDS. Moreover, attempting to avoid dealing with intrusive thoughts concerning future AIDS risk was associated with greater immune system decrements in asymptomatic HIV-positive men. The use of coping strategies such as extreme denial or acceptance were both associated with an accelerated disease course, while a certain degree of distraction (and perhaps low rumination about the disease) was associated with a slower rate of progression. Finally, people who remain socially isolated (and who may be the least comfortable in approaching their support network) appear to show the fastest progression of disease.

8.10.3.3 Psychosocial Factors in Long-term Survivors of AIDS

Another research strategy for establishing salubrious psychosocial factors in HIV-infected individuals has been to document the characteristics of those who substantially "outlive" their prognosis after a diagnosis of AIDS. This research has been reviewed by Ironson and colleagues (Ironson et al., 1995). The CDC currently estimates median survival time after an AIDS diagnosis (by the 1987 symptomatic criteria) to be 18–20 months (CDC, personal communication 1994; Eickhoff, 1994), a number that increases slowly each year as better diagnostic and treatment options become available. The CDC defines "long-term survivors" of AIDS as persons who survive twice the median expected time. Only a few studies of the psychosocial characteristics of long-term survivors of AIDS (defined by clinical symptoms) have been done, and as Ironson and colleagues note, almost all of these have been cross-sectional (Ironson et al., 1995). Ironson and her colleagues did, however, find a good deal of consensus on the existence of several different psychosocial characteristics of these individuals, noting four psychosocial adjustment strategies (Ironson et al., 1995): (i) healthy self-care behaviors; (ii) a sense of connectedness; (iii) a sense of meaning and purpose; and (iv) maintaining perspective. The first factor included three components—medical care, a healthy lifestyle, and an awareness and ability to take action to meet personal needs. The second factor, maintaining connectedness, is closely related to the maintenance of social support. Having at least one confidant is part of this factor, as is being able to communicate openly about concerns and, for homosexuals, disclosing a gay lifestyle. This is interesting in light of the findings of Cole and colleagues (Cole et al., 1996). The third factor, maintaining a sense of meaning and purpose, ties into the notion of having something to live for and, thus, represents a cognitive appraisal factor. Ironson and colleagues note that having an optimistic attitude, (or conversely being low on negative expectancies) are all a part of this. Some long-term survivors actually report finding new meaning as a result of being HIV-positive (Schwartzberg, 1994). Still others find meaning in their relationship with a higher power, or spirituality/religion as they define it (Woods, Antoni, Ironson, & Kling, 1996). The final factor is maintaining perspective. A failure to maintain perspective is represented by depression, negative affect, and hopelessness. Ironson et al. (1995) note that accepting the reality of an AIDS diagnosis without seeing it as an imminent death sentence is part of this perspective, as is believing one can live with AIDS, realizing AIDS is episodic in nature, and remembering that AIDS usually includes periods of good health. Using selective distraction as a coping strategy and not allowing AIDS to become the sole focus of one's life captures the essence of this factor. Ironson et al. (1995) conclude that maintaining perspective is quite close to the idea that balance is very important. They cogently use the optimism/negative expectancies construct and the denial/acceptance construct to point out that the extreme at either end is probably the least functional. It remains to be determined which psychological and biological mechanisms might explain the ways in which these four long-term survivor strategies relate to health outcomes in HIV-infected people.

8.10.4 INTERVENTIONS, ADJUSTMENT, AND HEALTH COURSE IN HIV INFECTION

8.10.4.1 Health Psychosocial Interventions with HIV-infected People

Since 1990 a small collection of studies have examined the effects of psychosocial interventions in HIV-infected populations. These studies used both psychological and immune measures as dependent variables, although none of them have completed long enough follow-up periods to clearly establish a health/disease progression effect. Most of these interventions employ cognitive behavioral techniques and operate in a group-based format. Comprehensive reviews of the psychological effects (Chesney & Folkman, 1994), and immune and health effects (Ironson et al., 1995) of psychosocial interventions in HIV populations are now available.

The psychological, immune, and health effects of psychosocial interventions in HIV-infected individuals are summarized in Table 1. Studies included in this table are restricted to those that monitored intervention-related changes in both psychological and immunologic status. The first study to examine the effects of stress management intervention on psychological and immune status in HIV-infected individuals was conducted by Coates and colleagues at the University of California at San Francisco (Coates, McKusick, Stites, & Kuno, 1989). They randomized 64 HIV-positive gay men to either an 8-week stress management training program or a control group. The intervention consisted of systematic relaxation (with take-home tapes), health habit education (diet, rest, exercise, drug and alcohol use, smoking), and skills for managing stress. While the intervention appeared to change sexual behavior (significantly fewer sexual partners), there were no effects on enumerative or functional immune measures. The panel of immune assays included: CD4 cells CD4/CD8 ratio, NKCC, lymphocyte response to con A, candida antigen and CMV. Psychological changes in the intervention or control groups were not reported though the authors acknowledge that the protocol they used may have been ineffective in reducing stress.

Another study which had some positive effects on psychosocial variables, but no effect on CD4 cell number, was done by Auerbach and colleagues (Auerbach, Oleson, & Soloman, 1992). Twenty-six symptomatic seropositive gay men were randomized to an 8 week behavioral medicine intervention, thermal biofeedback, guided imagery, and hypnosis, or a wait-list control group. The intervention reduced self-reported symptoms of HIV (fever, fatigue, pain, headache, nausea, and insomnia) and increased vigor and hardiness relative to controls, but did not change anxiety or depression. The authors speculate that if they had selected a more distressed HIV-infected sample they may have obtained changes in immune status variables and anxiety and depression measures. It is also possible that stress management interventions may work best if the groups start out with high stress or encounter a stressor during the course of the intervention. The most appropriate way to evaluate the effects of these types of interventions might be to test them in the context of either high distress states or measurable recent or ongoing stressful events (e.g., bereavement, diagnosis notification) and to include a comparison group of HIV-negative controls.

8.10.4.2 Stress Management Intervention Effects at Different Critical Points in HIV Infection

Some of the most well-documented behavioral interventions applied to HIV-infected individuals have attempted to use procedures that reduce distress, promote self-efficacy, and encourage the use of active coping strategies. Operating from a chronic disease-PNI rationale we have hypothesized that if behavioral interventions can retard or normalize declines in immune status by bringing about these psychosocial and behavioral changes, then they may be able to forestall the onset of disease complications, such as opportunistic infections and neoplasias (see Figure 1). Our group developed a 10-week CBSM intervention for HIV infection that was based specifically upon the psychosocial sequelae that have been reviewed previously (Antoni, Baggett et al., 1991). For some HIV-infected people these sequelae include being faced with a wide variety of chronic, uncontrollable, and unpredictable stressors (e.g., such as changes in health, job status, health insurance, and medical costs) and a loss of social support resources which is triggered by their own withdrawal, the death of close friends, or the responses of friends and family. These are likely to persist across and grow in magnitude over the course of the infection (see Hoffman, 1991).

This model reasoned that the combination of multiple uncontrollable burdens and declining coping resources may overwhelm HIV-infected persons" previously adequate direct coping strategies such as active coping, positive appraisals of burdens, problem-solving, and seeking social support, resulting in the adoption of more indirect strategies such as avoidance

and denial, on the one hand, and substance use and possibly risky sexual behaviors on the other. One self-defeating "loop" that this model highlights follows: the infected person's awareness of the ineffectiveness of their coping modes and strategies may increase their sense of low self-efficacy, helplessness, and hopelessness, which in turn perpetuates social isolation, depressive symptoms, continued substance use, and other negative health behaviors.

The intervention that was developed addresses each of these domains by enhancing self-efficacy and perceived control, teaching adaptive coping strategies, and improving social support availability, satisfaction, and utilization (Antoni, Schneiderman & Ironson, in press). This program teaches participants a variety of active coping strategies (e.g., cognitive restructuring, relaxation exercises, assertive responses) and may enhance their psychological functioning by increasing perceptions of self-efficacy, personal control, and mastery (Fishman & Loscalzo, 1987); changing maladaptive cognitive distortions (Simons, Garfield, & Murphy, 1984); modifying stressor appraisals and providing the person with an available coping response (Turk, Holzman & Kerns, 1986); decreasing a sense of hopelessness (Rush, Beck, Kovacs, Weisenberger, & Hollon, 1982); and increasing the availability and utilization of social support networks (Vachon, Lyall, Rogers, Freedman, & Freedman, 1980).

This CBSM intervention program uses 10 weekly modules to address these aims as follows: (i) to increase personal awareness by providing information on sources of stress, the nature of human stress responses, and different coping strategies used to deal with stressors; (ii) to teach anxiety reduction skills such as progressive muscle relaxation and relaxing imagery; (iii) to modify maladaptive cognitive appraisals using cognitive restructuring; (iv) to enhance cognitive, behavioral, and interpersonal coping skills through coping skills training, assertion training, and anger management techniques; and (v) to provide a supportive group environment and increase utilization of social support networks. The effectiveness of this intervention was systematically evaluated in different cohorts of HIV-infected persons who were dealing with different landmark challenges known to occur during the infection and focused on specific "critical points" that these HIV-infected people were passing through. The rationale underlying this approach is that HIV infection comprises not only a "spectrum" of diseases, but also a spectrum of psychosocial challenges that change over time. At least four, somewhat artificial, critical points can be used to characterize these challenges: (i) responding to the initial diagnosis of seropositivity; (ii) adjustment to being infected during the early asymptomatic period when individuals are still healthy; (iii) adjustment to the experience of HIV-related symptoms that are not life-threatening but do impact the quality of life; and (iv) adjustment to a diagnosis of AIDS (Lutgendorf, Antoni, Schneiderman, & Fletcher 1994).

8.10.4.2.1 The initial HIV seropositive diagnosis

In the first set of studies, 65 gay men who did not know their HIV serostatus were randomly assigned to either a CBSM intervention, an aerobic exercise intervention, or a control group. After 5 weeks of participating in one of these conditions, blood was drawn for antibody testing and the men received news of their serostatus 72 hours later. The intervention continued for another 5 weeks (10 weeks total) and the men were followed through the initial "adjustment" period. Across the notification period the HIV-positive controls showed significant increases in anxiety and depression, whereas the HIV-positive CBSM subjects showed no significant changes in anxiety, or depression scores (Antoni, Baggett et al., 1991). The same buffering effect was present for the HIV-positive men assigned to the aerobic exercise group (LaPerriere et al., 1990). With respect to immune findings, the HIV-positive controls showed slight decrements in responsivity to PHA, NKCC, and NK cell counts pre- to postnotification (with no change in CD4 counts). In contrast, the HIV-positive CBSM subjects had significant increases in CD4 and NK cells and slight increases in PHA responsivity and NKCC, thus showing a "buffering" effect (Antoni, Baggett et al., 1991). Exercise had a similar buffering effect on several immune measures, though these are not reviewed in detail here (see LaPerriere et al. [1990] or LaPerriere et al. [1994]).

A 2-year follow-up of 23 HIV-positive men recruited from these studies was conducted by Ironson and colleagues (Ironson et al., 1994) to determine psychological predictors of disease progression to symptoms and death from AIDS. They found that distress at diagnosis, HIV-specific denial coping (5 weeks postdiagnosis minus prediagnosis), and low treatment adherence (poorer attendance at either CBSM or exercise groups, a lower frequency of relaxation practice during the 10 weeks for those in the CBSM, and not doing homework for those in CBSM group) all predicted faster disease progression. Increases in denial and better treatment adherence remained significant even after controlling for initial disease severity at study entry (CD4 number). Furthermore, decreases in denial and a greater frequency of relaxation home practice during the 10-week intervention period were predictive of higher CD4 cell counts and greater blastogenic responses to PHA at 1 year follow-up (Ironson et al., 1994). These findings suggest that those men who attended intervention sessions regularly, and dealt with their denial during the intervention period, were most likely to show longer term immune and health benefits.

There were also several consistent immune changes noted over the total 10 week period of intervention. The CBSM (and exercise) interventions were associated with a significant decrease in antibody titers to EBV-VCA and to HHV-6 as compared to assessment-only controls, whose antibody titers remained constant over the 10-week intervention period and elevated relative to healthy male laboratory controls (Esterling et al., 1992). An analysis of other psychosocial changes revealed that men in the control group showed significant decrements in social support during the postnotification period, whereas those in the CBSM group maintained their social support levels (Friedman et al., 1991). We also found that pre–postintervention decrements in social support were associated with greater declines in NKCC over a similar period (Antoni, Ironson et al., 1992) and that the reductions in EBV antibody titers during this period appeared to be mediated by increases in social support (Antoni et al., 1996).

8.10.4.2.2 The asymptomatic stage of HIV infection

Even asymptomatic HIV disease is accompanied by wide-ranging psychosocial challenges including the many uncertainties with regard to future health course and available resources. The former arises due to the unpredictable physical course of the HIV infection and the latter as a function of uncontrollable stressors such as impaired occupational and social functioning, decreased earning power, high costs of medical care, complex medical treatments, difficulties with self-care, multiple bereavements, and declining social supports (Blendon & Donelan, 1988; Ginzburg & Gostin, 1986; Redfield & Burke, 1988; Walkey et al., 1990).

The effects of CBSM intervention have been examined with gay men who knew of their HIV-positive status for at least 6 months, but were still asymptomatic. Although their physical functioning had not yet been affected by the virus, knowledge of their positive serostatus, and its eventual implications, had affected their lifestyle, behaviors, and sense of well-being. Elsewhere the types of issues that these men were reporting have been described in greater detail (Lutgendorf, Antoni, Schneiderman, Ironson et al., 1994). Some issues included reluctance to terminate relationships, hesitating to have sex with someone who was uninfected for fear of infecting them, deciding to disclose HIV status to family members, and making job and career transitions. The predominant emotional experiences reported by these men included anger, fear, loss, and uncertainty.

The 10-week CBSM intervention developed for these asymptomatic men was specifically adapted to address these issues (Antoni, Ironson et al., 1992). The early part of the intervention maintained its psychoeducational focus, with sessions on HIV and the stress response, cognitive appraisals, refuting, and replacing cognitive distortions. For this cohort, the group sessions discussing impending notification and postnotification concerns were replaced with a session dealing with unfinished issues related to seropositivity notification and notification of others regarding one's seropositivity. Behavior change, assertiveness, and social support were addressed extensively in these group sessions, especially strategies for eliciting social support. From a sample of 23 men, 11 were randomized to CBSM and 12 to an aerobic exercise program, each lasting 10 weeks. Because this was a pilot study there was no control condition. Participants in CBSM significantly reduced their anxiety, depression, anger, fatigue, and confusion levels, as well as increasing feelings of vigor (Antoni, Ironson et al., 1992). They also reported increased use of adaptive coping strategies, active coping, planning, and acceptance, and decreases in several maladaptive coping strategies such as mental disengagement and denial. These individuals also revealed significant increases in blastogenic responses to PHA and NKCC.

Other groups have also reported significant reductions in distress (Chesney et al., 1996a, 1996b; Kelly et al., 1993; Mulder et al., 1994) and improvements in self-efficacy (Chesney et al., 1996a, 1996b) with cognitive behavioral interventions in asymptomatic HIV-infected men. Kelly and colleagues randomized participants to either cognitive-behavioral group intervention, social support group intervention, or no-treatment, and found significant reductions in depression, hostility, and somatization in the cognitive-behavioral groups, as well as the social support group, compared to controls. The cognitive-behavioral group was somewhat more effective at reducing drug use (Kelly et al., 1993). Mulder and colleagues compared cognitive-behavioral group intervention and existential experiential group intervention in

HIV-infected gay men and found that both groups reduced distress and depressive symptoms compared with a wait-list control condition (Mulder et al., 1994). Finally, Chesney et al, compared the effects of a CBSM group intervention (Coping Effectiveness Training (CET)) (Chesney et al., 1994; Folkman et al., 1991) with an information group and a wait-list control group, and found that CET significantly increased self-efficacy and decreased perceived stress and burnout compared to the other two conditions (Chesney et al., 1996a, 1996b).

8.10.4.2.3 The pre-AIDS symptomatic stage of HIV infection

The effects of a group-based CBSM intervention have also been evaluated in HIV-positive gay men who are dealing with the symptoms of the infection. Forty HIV-infected gay men who had mild symptoms (category B of the 1993 CDC definition) were randomly assigned to either the CBSM intervention or a modified wait-list control group in which they complete a 10 week waiting period before being reassessed and provided a one day CBSM seminar. Across the 10 weeks the CBSM group showed a significant decrease in depression, anxiety, and antibody titers to HSV-2 (Lutgendorf, Antoni, Ironson, Klimas et al., 1997). Moreover, the 10 week decreases in HSV-2 antibody titers were strongly associated with the degree to which participants lowered their depression scores on the Beck Depression Inventory (BDI; Beck, Ward, Mendelson, Mock, & Erbaugh, 1961) over this period. The control group showed no such changes in depressive symptoms or antibodies to HSV-2. Subsequently, conducted path analyses revealed that the effects of CBSM on HSV-2 antibody reductions appeared to be mediated by the intervention-associated depression changes (Antoni et al., 1996). Since this structured intervention was designed to increase cognitive and behavioral coping skills and support among group members, we next examined the relative contribution of intervention-related changes in coping skills and social support to reductions in dysphoria, anxiety, and distress-related symptoms over the study period. Those randomized to CBSM showed significant improvement in cognitive coping strategies, such as positive reframing and acceptance, as well as in total perceived social support provisions compared to a wait-list control condition (Lutgendorf et al., 1996). Cognitive coping changes, specifically acceptance of the HIV infection, were strongly related to lower dysphoria, anxiety, and total mood disturbance in this sample. Path analyses suggested that changes in social support, and in cognitive coping strategies, appear to mediate the effects of the CBSM intervention on the changes in distress noted during the intervention. These results suggest that cognitive coping strategies and social support factors can be modified by psychosocial interventions. These changes may in turn be important determinants of psychological well-being and quality of life during symptomatic HIV infection.

8.10.4.2.4 Full-blown AIDS

To date, the bulk of the published empirical studies evaluating the efficacy of psychosocial interventions with HIV-infected people have focused on gay men at the earlier stages of the infection. While there is a growing literature documenting those psychosocial factors that are predictive of both psychological adjustment and physical health course in AIDS patients (e.g., long-term survivor literature reviewed in Ironson et al. [1995]), little or no work exists testing the effects of various interventions with patients who have progressed to AIDS. What we do know is that the onset of AIDS may be accompanied by a lessening of psychological distress from the levels experienced by symptomatic (pre-AIDS) HIV-infected men (Dilley et al., 1985; Tross & Hirsch, 1988). This may reflect a relief from the unpredictability of not knowing if and when the first signs of AIDS may occur.

With the steady progression of HIV infection to more and more serious symptoms, and eventually AIDS, individuals go through a continual process of emotional crises, recycling through the stages that Kubler-Ross (1969) originally noted as comprising the dying process (Lutgendorf, Antoni, Schneiderman, & Fletcher, 1994). Moreover, HIV-infected patients may have emotional reactions that are more intense and labile than those described by Kubler-Ross (Hoffman, 1991). The high percentage of HIV-infected individuals diagnosed with adjustment disorders is a testimony to the difficulties encountered as these people try to come to terms with their illness and its impact on their lives (Hoffman, 1991). While it is clear that these individuals are in need of psychosocial services, one must be cautious in applying what has been learned from asymptomatic and early-stage populations to those with AIDS. There is a lack of empirical studies evaluating the effectiveness of psychosocial interventions such as CBSM or other approaches such as Expressive Supportive therapy conducted in a group or individual-based format with individuals at this stage of the infection. It may be that those with AIDS may find structured CBSM techniques useful, but may also require additional emotional support. For these individuals a therapeutic plan that combines a group-based stress reduction intervention with individual-based therapy directed toward these existential issues may be very useful. An optimal therapy plan may also involve pharmacologic treatment blended with the psychosocial intervention.

8.10.4.3 Common Features of Psychosocial Interventions in HIV Infection

8.10.4.3.1 Relaxation aspects

It is noteworthy that many of the psychosocial intervention studies with HIV-infected persons have utilized some form of relaxation-based technique as part of the intervention protocol. This is relevant given the great deal of distress and anxiety that these people experience. Relaxation strategies are also salient given the reasonably large literature base relating relaxation to improvement in immune system functioning (e.g., Ironson et al., 1995; Kiecolt-Glaser et al., 1985, 1986). With regard to HIV infection, one of these studies found that frequency of home relaxation practice was related to better immunological functioning and slower disease progression in HIV-infected men (Ironson et al., 1994).

Another study examined alternate ways of inducing relaxation in HIV-infected individuals (Ironson et al., 1996)—massage therapy—because of its expected relaxing effects, and because it is easy to monitor objectively how much massage someone is getting. HIV-infected gay men showed a significant increase in NK cell number, NKCC, the soluble CD8 receptor, and the cytotoxic subset of CD8 cells during the weeks of daily massage intervention compared to the same men's values during a no-massage period. These men also showed significant decreases in 24 hour urinary cortisol output during the intervention period, suggesting that distress decreases and/or relaxation increases may have mediated these immunologic changes. Indeed, significant decreases in anxiety and increases in a sense of relaxation were also observed, which were both correlated with increases in NK cell number. This study suggests that the relaxation components of CBSM interventions noted previously may contribute directly to both the psychological and immunologic changes experienced by the participants. Psychosocial interventions used with HIV-infected persons use many other techniques in addition to relaxation and also vary considerably in terms of format and theoretical orientation. It is possible to examine some of the parameters on which these approaches converge and diverge.

8.10.4.3.2 Delivery format

Regarding delivery format, it is important to note that most of the psychosocial interventions evaluated with HIV-infected persons (including those involving aerobic exercise training [LaPerriere et al., 1990]) have been conducted in a group format (Ironson et al., 1995). These CBSM interventions typically employed groups of approximately 6–8 participants facilitated by two group leaders. The sessions were conducted in comfortable rooms, ran about 2–2.5 hours in duration, and ran on a weekly basis over a 10-week period. While there was some variability in terms of the duration of programs evaluated across different research groups (range = 8–12 weeks), the number of participants, group leaders, and session length and frequency were quite similar. Because of the fact that these sessions were conducted in a group format, little is known about the effects of these sorts of techniques with HIV-infected persons when delivered as individual-based psychotherapy sessions or self-help approaches.

8.10.4.3.3 Treatment orientation

Different treatment orientations to psychosocial interventions have been compared in HIV-infected persons by one group in the Netherlands (in collaboration with the University of Miami). They examined the influence of treatment orientation by comparing the psychological (Mulder et al., 1994) and immunologic (Mulder, Antoni, Emmelkamp et al., 1995) effects of one group-based intervention using a cognitive-behavioral orientation vs. one using an existential/experiential orientation in HIV-infected gay men. These men were recruited from a large cohort study conducted through the Amsterdam Municipal Health Center. The cognitive-behavioral therapy (CBT) intervention included training in cognitive restructuring, relaxation exercises, behavior change, assertiveness skills, coping fit for controllable vs. uncontrollable stressors, and information on stress responses. As such, it was quite similar to the CBSM interventions described previously. The experiential therapy (ET) condition was less structured and focused on increasing awareness of the here and now, of their inner experiential process, and restoring congruence between emotional, cognitive, and behavioral schemata. The intervention also attempted to help participants deal with a shortened life perspective and anxiety about future illness and death. Despite the differences in theoretical orientation the authors note that both interventions were designed to reduce stress, improve coping, build social support, and encourage emotional expression. They found that both (CBT and ET) conditions were associated with significant decreases in POMS total mood disturbance, and BDI scores compared to the controls, though there were no changes in coping style, social support, or emotional expression over the intervention period.

Mulder and colleagues compared the 26 men randomized ultimately to either CBT or ET with men from the Amsterdam cohort study who did not participate in the intervention study for differences in slope of immune changes that had occurred over the period after the intervention (Mulder, Antoni, Emmelkamp et al., 1995). Those intervention group participants with the largest decreases in distress, between the beginning of either intervention and 9 months later, showed the least decline in CD4 cell counts over a 2-year follow-up period from the beginning of the intervention. These findings suggest that while theoretical orientation may not determine the psychological improvements gained by HIV-infected men participating in group-based psychosocial interventions, the size of treatment-related reductions in distress may be predictive of longer-term health benefits. This interpretation seems to be in line with the findings reviewed previously (Antoni, Baggett et al. [1991] for short-term effects and Ironson et al. [1994] for longer-term effects).

8.10.4.4 Summary of Completed Studies of Psychosocial Interventions with HIV-infected Persons

Here we summarized the qualities characterizing the psychosocial intervention studies with HIV-infected individuals that were completed between 1989 and 1997. These studies recruited moderate sized samples that were approximately equally distributed across experimental conditions usually resulting in 10–30 people actually receiving the intervention in any single trial. While individuals participating in these studies were all gay or bisexual men, congruent with the predominant AIDS incidence patterns occurring in the 1980s, it should be noted that women now make up nearly 15% of all AIDS cases and current incidence patterns for HIV infection suggest that this proportion will increase. Therefore, these studies need to be replicated with other HIV-infected populations such as indigent women.

Of the interventions tested to date, most were conducted in groups, used trained facilitators or therapists, and met at least once weekly over periods of 8–12 weeks. Since the studies evaluating these interventions were designed to test their immediate efficacy, cohorts were typically assessed at single time points at the beginning and end of the intervention period. At least two studies followed subjects over a 2-year postintervention period (Ironson et al., 1994; Mulder et al., 1995).

While the results of this set of studies are not entirely consistent, they suggest the potential efficacy of psychosocial interventions for increasing psychological adjustment, immune functioning, and health status in HIV-infected people at early and middle stages of the disease who are dealing with mounting stressors. Less is known about the effects of these interventions with people at the more advanced stages of the disease. One study focused specifically on how a time-limited CBSM intervention could moderate the acute impact of learning one's HIV serostatus for the first time (Antoni, Baggett et al., 1991), while the remainder have examined how psychosocial interventions can improve psychological functioning in people dealing with the more chronic stress of having had HIV for a number of years (Auerbach et al., 1992; Coates, McKusick et al., 1989; Ironson et al., 1995; Mulder et al., 1994). The most consistent trends among the psychological effects of these interventions are: a decrease in distress and depressed affect; a decrease in the use of avoidance and denial as coping strategies; an increase in the use of acceptance and positive reframing strategies; and an increase or maintenance of social support provisions.

While CBSM intervention has been shown to reduce antibodies to herpes viruses and to modulate NKCC, no direct effects have been observed on HIV disease progression markers. Three group-based stress management interventions reported no significant impact on CD4 cell counts (Auerbach et al., 1992; Coates, McKusick et al., 1989; Mulder, Antoni, Emmelkamp et al., 1995), but none of these measured herpes virus antibodies or NKCC, which were the measures found to be most responsive to change in some of the other studies (Esterling et al., 1992; Ironson et al., 1996; Lutgendorf, Antoni, Schneiderman, & Fletcher, 1994). Ironson et al. (1995) note that no studies have tested the long-term effects of these interventions on 5- or 10-year survival, although one study with a small sample showed that intervention-related variables (denial coping reductions and greater treatment adherence) were predictive of 2-year survival (Ironson et al., 1994). Another study (Mulder, Antoni, Emmelkamp et al., 1995) showed distress changes (which can often be modified by psychosocial interventions) were related to changes in CD4 counts over a similar 2-year period. However, it should be noted that "assignment to a psychosocial intervention" has not been causally related to a slower rate of disease progression or greater survival time in HIV-infected persons. This lack of a causal effect may be due to the limited statistical power offered by the small samples that have been studied to date. Clinical trials that utilize hundreds of participants may be necessary to capture the effects of psychosocial interventions on the health course of this disease. It is also possible that measures of immune function might be more sensitive to the effects of stress-reducing psychosocial interventions than lymphocyte counts because stress hormone interactions with receptors that mediate cell activity and certain immune functional indices may be especially relevant to the pathophysiology of HIV infection in particular. Finally, it has been suggested that health psychology interventions possessing cognitive and behavioral elements, similar to those just noted, may be quite useful in addressing other aspects of HIV infection, such as nutritional disorders, pain, sleep problems, and medication adherence, all having a potentially huge impact on the quality of life of infected individuals (Sikkema & Kelly, 1996). It will be important to incorporate these additional variables into intervention protocols conducted in the future as more and more people live longer and longer with this disease.

8.10.5 CONCLUSION

This chapter has summarized the rationale and empirical support for the role of health psychology in the context of HIV infection and AIDS. Based on this work it is plausible to suggest that psychosocial targets of interventions should include reductions in distress and depression, as well as avoidance, denial, and rumination as methods of dealing with the chronic stress of the infection. Equally important intervention targets would involve increasing active coping and a sense of social attachment as important stress buffers. Several studies are underway which further examine the effects of psychosocial interventions on psychological adjustment, immune status, and disease course in HIV-infected individuals. There are several reasons to be encouraged by the trends that are apparent across ongoing investigations of psychosocial interventions in HIV-infected populations.

First, all of the studies use standardized time-limited interventions (10–17 weeks) that have been "manualized" with specific treatment modules and criteria for therapist training and implementation (e.g., Antoni, Schneiderman, & Ironson, in press). In some cases these interventions follow a CBSM orientation and in others a more experiential-existential approach is utilized while, in others, CBSM and experiential techniques have been integrated into the same intervention condition. The efficacy of these different treatment orientations may ultimately be shown to vary systematically as a function of the disease stage and demographic characteristics of the targeted population.

Second, these investigations are each recruiting people who meet specific inclusion and exclusion criteria that are similar across studies. Specifically, the samples are largely gay men at the early to middle stages of the infection (pre-AIDS symptoms and a restricted range of CD4 counts) who are dealing with similar psychosocial issues. Shifting demographic patterns of the HIV/AIDS epidemic make it imperative to develop techniques to help other HIV-infected populations, such as women of color, manage their disease. One study, led by Antoni, Greenwood, and Schneiderman in Miami, is examining the effects of a 10-week CBSM intervention in HIV-infected African-American women who are developing the first symptoms of the infection. Another trial is evaluating the effects of a similar intervention in women who have already developed AIDS. Clearly, a next step is to develop psychosocial interventions to address secondary prevention issues in the growing number of HIV-infected injection drug users.

Third, each study is assessing the psychosocial effects of these interventions with a collection of well-validated instruments designed to track changes in distress and depression as well as intermediary psychosocial variables such as coping, social support, and stressor appraisals. In most cases, the most reliable instruments have been employed in these batteries supplemented with more specific measures designed to tap the most salient areas of participants" lives.

Fourth, most of these studies currently being done reflect an excellent breadth of immunologic measures (including qualitative and quantitative indices). For instance, several studies are now assessing the effects of psychosocial interventions on NKCC and blastogenic responses to PHA. Several studies are also examining changes in IgG antibody titers to a panel of relevant herpes viruses (e.g., EBV, HHV-6, CMV, HSV) and assessing serum neopterin as a subclinical disease progression marker. In the future it is likely that assessments of HIV viral load will join this list of assays as a way to monitor treatment-related changes in disease status. It is also imperative that more disease- and antigen-specific immunologic measures be incorporated into assessment protocols to better understand specific pathophysiologic links between psychological changes and health course.

Fifth, all of the studies are tracking the effects of their interventions on clinical health changes using standardized staging procedures and criteria (Centers for Disease Control, 1993). Due to the relatively large sample sizes, these studies should be able to assess long-term effects on survival. All of these studies are also monitoring changes in several other behavioral measures such as sexual behaviors, substance use, physical activities, sleep, and medications. Information about changes in these additional measures, over the course of the interventions, may be useful for clarifying the mechanisms underlying treatment changes in affective, immunologic, and health endpoints, as well as representing important quality of life changes that may be likely to occur following participation in psychosocial interventions. Once completed these studies may provide efficacy data supporting the initiation of larger clinical trials as well as informing behavioral scientists about the psychosocial mechanisms underlying psychological adjustment, physiological functioning, and health preservation in this chronic disease.

Sixth, the arrival of protease inhibitors and triple combination therapies to the treatment arena has brought about important improvements in the health care of AIDS patients (Lewin, 1996; Schneiderman et al., 1997). The resulting treatment philosophy for HIV and AIDS increasingly views HIV infection as a chronic disease in which patient management is critical. It is quite reasonable to propose that psychosocial interventions can be an essential part of this management (Schneiderman et al., 1997). The key here is consistent adherence to a demanding medication schedule in the context of an already stressful daily existence. We now know, for example, that once patients are given protease inhibitors, medication protocols must be rigidly followed with respect to drug schedules and food intake or the virus may mutate and become drug resistant (Lewin, 1996). Failure to adhere to specific guidelines cannot only compromise the effects of the particular protease inhibitor being used, but can also reduce the efficacy of other related compounds to which cross-resistance has developed (Lewin, 1996). Psychosocial interventions that provide information, skills, and support to patients can facilitate adherence to difficult medication protocols. Since interventions such as CBSM can decrease denial and depressed affect, they may, in turn, decrease negative health behaviors and facilitate adherence to medical treatment regimens. It has been shown that better adherence to a stress management protocol is predictive of a slower rate of disease progression (Ironson et al., 1994). The improvements in immune function that have been associated with these psychosocial interventions raise the interesting question of whether CBSM can help reconstitute the compromised immune system once pharmacologic agents such as protease inhibitors have contained the virus. These latter questions constitute the focus of the ongoing work using health psychology strategies to address contemporary secondary prevention issues in the growing populations of HIV-infected persons who are attempting to manage their disease.

8.11.1 INTRODUCTION

8.11.1.1 The Conditions

Diabetes mellitus is not a single disorder but a heterogeneous group of disorders. All forms are characterized by hyperglycemia and disturbances of carbohydrate, fat, and protein metabolism which are associated with absolute or relative deficiencies of insulin action and/or insulin secretion. The World Health Organization (WHO) developed a now widely accepted classification of the disorder, largely based on clinical characteristics (see Table 1, WHO, 1985).

Insulin is needed to allow glucose to pass from the blood into most of the body cells. Only the cells of the brain and central nervous system can use glucose from the blood in the absence of insulin. Without insulin, most body cells metabolize substances other than glucose for energy. However, fat metabolism in the absence of glucose metabolism, creates ketone bodies which are poisonous and their build up is associated with hyperglycemic coma. In the absence of sufficient insulin, unmetabolized glucose builds up in the blood. Water is drawn from body cells by osmosis to dilute the highly concentrated blood, and is then excreted along with much of the glucose, once the renal threshold for glucose (usually 10 mmol/L) is exceeded. Dehydration follows.

The characteristic presenting symptoms of diabetes are fatigue, extreme thirst, excessive urination, unexplained itch, recurrent infections (e.g., boils and thrush), and otherwise unexplained weight loss. These symptoms recur if treatment is not controling the condition adequately.

Complications of diabetes are responsible for considerable morbidity and mortality. The acute complications of diabetes are hypo- and hyperglycemic coma and infections. The chronic complications include microvascular complications such as retinopathy and nephropathy, and the macrovascular complications of heart disease and stroke. Diabetes mellitus is the commonest cause of blindness and renal failure in the UK and the USA. Other common complications include autonomic and peripheral neuropathy. A combination of vascular and neuropathic disturbances results in a high prevalence of impotence in men with diabetes. Peripheral neuropathy causes lack of sensation in the feet which can cause minor injuries to go unnoticed, become infected and, with circulatory problems obstructing healing, ulceration and gangrene are serious risks and amputation is not uncommon. Evidence from meta-analysis of studies of the relationship between glycemic control and microvascular complications (Wang, Lau, & Chalmers, 1993), and from the longitudinal multicenter Diabetes Control and Complications Trial (DCCT) in the USA (DCCT Research Group, 1993), have established a clear relationship between improved blood glucose control and reduction of risk of retinopathy and other microvascular complications in insulin-dependent diabetes mellitus (IDDM). It is likely that there would be similar findings for noninsulin-dependent diabetes mellitus (NIDDM) though the studies did not include NIDDM patients. However, the DCCT included highly selected, well-motivated, well-educated and well-supported patients, cared for by well-staffed diabetes care teams involving educators and psychologists as well as diabetologists and diabetes specialist nurses.

It is a considerable challenge to obtain the goals of the intensively treated patients in the DCCT with the vast majority of people with diabetes given the more limited health care resources typically available in routine practice. If diabetes control can be improved without significant damage to quality of life, the economic, health, and quality of life savings associated with a reduction in complications in later life will be vast. Although some people who have had poorly controlled diabetes over many years do not develop complications, complications commonly arise after 15–20 years of diabetes and individuals in their 40s or even 30s may develop several complications in rapid succession. However, up until the early 1980s, patients had no way of monitoring their own blood glucose levels at home. Urine glucose monitoring only told them when their blood glucose had exceeded the renal threshold of approximately 10 mmol/L (i.e., was far too high), without being able to discriminate between the too high levels of 7–10 mmol/L or the hypoglycemic levels below 4 mmol/L.

Table 1 WHO (1985) classification of diabetes mellitus.

Types	*Description*
1.	Insulin-dependent diabetes mellitus (IDDM)
2.	Noninsulin-dependent diabetes mellitus (NIDDM) a. Nonobese b. Obese
3.	Malnutrition-related disorders
4.	Other types of diabetes associated with certain conditions and syndromes including: pancreatic disease, diseases of hormonal etiology, drug-induced or chemical-induced conditions, abnormalities of insulin or its receptors, certain genetic syndromes
5.	Gestational diabetes mellitus

NIDDM and IDDM are the most common forms of diabetes in first-world countries, with gestational diabetes also being common.

Clinics relied on random blood glucose testing and there were no measures of average blood glucose over a longer period. Since the 1980s there have been measures of glycosylated hemoglobin (GHb, HbA_1, or HbA_{1c}) which indicate average blood glucose over a six to eight week period and measures of glycosylated protein, fructosamine, which indicates average blood glucose over a two-week period. Blood-glucose meters for patients were first introduced in the early 1980s and the accuracy and convenience of the meters and the reagent strips they use has improved dramatically since early models. By the late 1990s blood-glucose monitoring is part of the daily routine for most people using insulin in developed countries. Blood-glucose monitoring is less often prescribed for tablet- and diet-alone-treated patients, financial reasons probably being allowed to outweigh the educational value of accurate feedback in improving control long term. The reduced risk of hypoglycemia and diabetic ketoacidosis in NIDDM patients not using insulin means that acute crises rarely arise in these patients though their risk of long-term complications is at least as great as in IDDM and might be expected to be reduced if feedback from blood-glucose monitoring were provided.

8.11.1.2 Insulin Dependent Diabetes Mellitus

IDDM, also known as juvenile-onset diabetes, ketosis-prone diabetes, or Type 1 diabetes, is the commonest form of diabetes in children and young adults of European origin. Age at clinical onset of the condition is usually under the age of 30 years.

People who develop IDDM lose the ability to produce insulin altogether. Diagnosis and treatment with exogenous insulin is often followed by a "honeymoon" period when endogenous insulin production restarts and the exogenous insulin doses required are reduced and, occasionally, can be discontinued. This is, however, always only a temporary respite. Thereafter, exogenous insulin, usually delivered by subcutaneous injection, will be needed continuously throughout the lifetime of a person with IDDM. If insulin therapy is discontinued, even for a few days, ketotic coma will develop and, if not treated, will result in death.

The onset of IDDM is abrupt, with severe thirst, excessive urination, and dramatic weight loss. Individuals usually present to the doctor with one or more of these symptoms and an elevated blood glucose level. They will also have glucose, and possibly ketones, in their urine. This combination indicates diabetic ketoacidosis and is a potentially fatal medical emergency. Diagnosis is made clinically and confirmed on the basis of an elevated blood glucose concentration (> 6.7 mmol/L).

IDDM can be managed by balancing injected insulin, carbohydrate intake, and energy expenditure. The goal of treatment is to maintain blood glucose levels as close to the normal range as possible (i.e., 4–6 mmol/L) in order to reduce the risk of chronic complications, while also avoiding the dangers of blood glucose levels falling to hypoglycemic levels. To achieve this goal, people with IDDM will usually need to measure their blood glucose levels several times daily. In the 1980s and early 1990s, two injections a day were commonly used by IDDM patients. However, more recent evidence has shown that more intensive therapy, with up to five injections per day, is associated with reduced risk of chronic complications (DCCT Research Group, 1993; Wang et al., 1993) though at the price of threefold increases in occurrence of severe hypoglycemic episodes (DCCT). Intensive insulin regimens have become more commonly used in the 1990s and this trend has been facilitated by the development of insulin delivery devices such as pen-injectors which simplify the task of administering insulin, and continuing improvements in blood glucose monitoring methods (Bradley, Christie, & Home, 1991). The dangers of hypoglycemia, which tend to be increased with the intensity of the insulin therapy, give increasing cause for concern. Severe hypoglycemic episodes cause acute behavior changes with behavior often becoming aggressive, and unless action is taken to increase the blood glucose levels, collapse and coma follow rapidly. Insulin-dependent individuals need to carry with them at all times glucose tablets or some other form of rapidly absorbed glucose so that they can respond to early signs of hypoglycemia by increasing their blood glucose levels and thus prevent a severe hypoglycemic episode.

8.11.1.3 Noninsulin Dependent Diabetes Mellitus

NIDDM, also known as maturity-onset diabetes or Type 2 diabetes, is the commonest form of diabetes worldwide (85% of cases in the developed world). Age at clinical onset of the disorder is usually over the age of 40 years.

People with NIDDM continue to produce insulin, but it is inadequate either in amount or in action to maintain their blood glucose levels in the normal range. With the development of the pathological process involved, patients first have asymptomatic glucose intolerance and then go on to develop diabetes mellitus. Unlike IDDM, the process of development of NIDDM is insidious. Individuals may have NIDDM for years before it is diagnosed.

Diagnosis may result from patients presenting with classical symptoms, or with one or more of the complications of diabetes, or diabetes may be found on routine medical examination (confirmed by oral glucose tolerance testing). Dietary management is the first choice of treatment for NIDDM. A low-fat weight-reducing high fiber diet will be recommended to those who are overweight and if weight can be reduced and maintained close to ideal weight it may be the case that no further treatment is required. The diet recommended is usually high in complex carbohydrates and fiber and low in refined carbohydrates in order to avoid rapid absorption of glucose and to maintain blood glucose at a more even level without peaks of hyperglycemia. Reduction in fats may also be recommended (particularly if the individual has abnormal lipid levels) with a view to lowering and maintaining triglyceride and cholesterol levels and thereby reducing the risks of cardiovascular disease which accompany NIDDM.

If glucose levels cannot be controlled adequately with diet alone, oral hypoglycemic agents are added to treatment. These tablets do not contain insulin which, being a protein, would be digested if taken orally, but rather act to stimulate production of endogenous insulin or to enhance the effectiveness of existing levels of insulin. A variety of oral hypoglycemic drugs are available, such as sulfonylureas and biguanides. These differ in their modes of action and side effects, for example, sulfonylureas may increase the risk of hypoglycemia. If adequate control of blood glucose cannot be achieved with diet and tablets, insulin is likely to be recommended. It is important to recognize that NIDDM patients using insulin are just as prone to severe hypoglycemia as IDDM patients. However, because in NIDDM there is limited endogenous insulin secretion, sufficient to allow some glucose metabolism, ketoacidosis and hyperglycemic coma are unlikely to develop if exogenous insulin is reduced or discontinued.

Although NIDDM is often misguidedly referred to as "mild diabetes," the risk of chronic complications is no less than that associated with IDDM. People with NIDDM are two or three times as likely to develop cardiovascular disease than people without diabetes and 75% die of cardiovascular disease. The life expectancy of people with NIDDM is, on average, reduced by a decade as a result of the disease. Although the later onset of NIDDM might be expected to reduce the risk of complications which are usually associated with raised blood glucose levels over 15 or more years, the insidious onset of NIDDM delays diagnosis, and chronic hyperglycemia over many years probably accounts for the many cases which are only diagnosed after the onset of complications.

8.11.2 IDDM: ETIOLOGY, RISK FACTORS, AND PREVENTION

IDDM is caused by the autoimmune destruction of insulin-producing beta-cells in the pancreas. The pathological process is probably initiated several years, sometimes even decades, before clinical onset by an interaction of genetic predisposition and environmental triggers (Zimmet, 1995). The incidence of IDDM has been reported to change with age, rising to a peak around puberty (Laakso & Pyörälä, 1985) with a second peak later in life (Krolewski, Warram, Rand, & Kahn, 1987). Altogether, more cases of IDDM are diagnosed in adulthood rather than in childhood (Vandewalle et al, 1993) and, in some studies, a higher incidence has been found in males than in females (Blohmé et al., 1992; Bruno et al., 1993). Marked geographical variation in IDDM incidence has been observed, varying from 35.3 per 100 000 inhabitants in Finland to 1.9 per 100 000 in Japan (Karvonen, Tuomilehto, Libman, & LaPorte, 1993). Differences in incidence between neighboring countries has led to the assumption that diet and lifestyle are important determinants of the disease (Green, Gale, & Patterson, 1992), but differences in the frequency of "diabetogenes" may also play a role. Since the 1970s the incidence of IDDM has doubled in Europe (Bingley & Gale, 1989) and is steadily increasing worldwide (Krolewski et al., 1987). However, most of the incidence data are only available for those with early onset before the age of 20 years. Since most cases are diagnosed during adulthood, it may be that the apparent doubling in incidence is due to a shift towards earlier clinical onset of diabetes rather than to an increase in the number of people developing IDDM at some point in their lives (Bingley & Gale, 1989).

8.11.2.1 Risk Factors in IDDM

A genome-wide search has revealed that more than 12 gene loci contribute to genetic susceptibility for IDDM (Todd, 1995). The genetic component of the condition is indicated by the 5% prevalence of IDDM in first degree relatives, compared with less than 1% in the general population (Bingley, Bonifacio, & Gale, 1993; Gorus, Anselmo, & Keymeulen, 1993), and the higher concordance rate for IDDM in identical than in nonidentical twins (Leslie & Elliott, 1994). Nevertheless, 90% of the new cases occur in individuals without a family history of diabetes (Bingley et al., 1993). These individuals, however, also carry certain predisposing genotypes. Genetic susceptibility is not sufficient to cause diabetes (Karvonen et al., 1993) since a majority of people with disease-associated alleles do not develop IDDM. Environmental agents appear to have an important role. The way in which the environment affects the pathogenesis is still unclear. It has been hypothesized that viral infection (Krolewski et al., 1987; Zimmet, 1995) and proteins in the diet (Gerstein, 1994) are important factors. Psychological stress may also have a role in increasing vulnerability to viral infection or impairing defense mechanisms against such infection, thereby facilitating the progression of the hidden pathological process. Clear evidence for such an effect is difficult to obtain, though suggestive evidence is available to support the notion that stress may contribute to the development of IDDM (see Bradley, 1988 for review). There is stronger evidence to suggest that psychological stress can trigger the onset of symptoms in a person in whom islet beta-cell damage is at an advanced stage (Bradley, 1988; Clayer, Bookless-Pratz, & Harris, 1985). Blood glucose levels already raised as a consequence of diminishing insulin production can be elevated further by neuroendocrine responses to psychological stress and tipped over the renal threshold to precipitate the overt symptoms of diabetes which would have appeared in due course without the occurrence of the stress.

Knowledge about the incidence of IDDM has developed as a result of national and regional registries (Karvonen et al., 1993). Standardized data are collected on previous exposure to environmental factors and occurrence of metabolic and genetic markers for new IDDM cases (Gorus et al., 1993). The long-term follow-up of at-risk families allows comparative studies of the cause and pathogenesis of the disease and can help clarify temporal, regional, and environmental variations in the incidence of diabetes (Diabetes Epidemiology Research International Group, 1988).

8.11.2.2 Prevention of IDDM

There is no cure for IDDM. Despite evidence that improved blood glucose control reduces the risks of complications and despite the development of increasingly effective insulins and more convenient delivery systems and monitoring devices, the complications of diabetes continue to present major health problems with massive personal, social, and economic costs. The possibilities of preventive strategies are therefore attracting considerable attention.

8.11.2.2.1 Primary prevention

The aim of primary prevention is to avoid the initiation of the hidden pathological process leading to IDDM. This strategy requires identification of genetically predisposed individuals and protection against avoidable environmental factors (e.g., nutritional or viral). Because of the lack of specific knowledge about the nature of these triggering factors, large-scale initiatives could lead to treatment of many people who might never develop IDDM (Palmer & McCulloch, 1991). The role of the diabetes registries is crucial in improving understanding of the interaction between genetic and environmental factors. A first attempt at primary prevention has been initiated in Finland (Akerblom et al., 1993), where the role of cows" milk proteins in the diet of young children is under investigation.

8.11.2.2.2 Secondary prevention

The preclinical phase of IDDM is accompanied by humoral, immune, and metabolic abnormalities. Much knowledge has been accumulated since the 1980s about the diabetes-predictive value of several of these early markers (Dotta, Dionisi, Farilla, & DiMario; 1996). Refining the use of these marker combinations would allow early diagnosis of diabetes and offers the possibility of secondary prevention with the aim of halting or delaying the progression of further destruction of the beta-cell mass by pharmacological intervention at an early stage of the pathological process.

The presence of antibodies against various diabetes-associated islet-cell autoantigens is considered to be one of the best indicators of a latent autoimmune disease process in the islets (Dotta et al., 1996), although the relation of these antibodies to the pathological changes is poorly understood. Data obtained in a representative sample recruited through diabetes registries show that at least one of these immunological markers is present in approximately 90% of the individuals at clinical diabetes onset and also in the vast majority of relatives in the preclinical stage (Gorus et al., 1997; Verge et al., 1996). The presence of more than one type of autoantibody greatly increases the risk of IDDM (Eisenbarth, Vergen, Allen, & Rewers, 1993). Metabolic markers can be detected in a later phase of the preclinical stage. A decreased early-insulin response to an intravenous glucose challenge and increased proinsulin levels can indicate impending clinical onset of IDDM. There are indications that combined presence of these biological markers can also be helpful in identifying preclinical IDDM in the general population (Hagopian et al., 1995). The early diagnosis of a hidden disease process creates the theoretical possibility of influencing the process pharmacologically in such a way that the clinical disease manifestation is prevented. Pilot studies in animal models and on a small scale in humans suggest that such an approach is feasible. Large-scale intervention trials have been initiated with nicotinamide and with insulin. It is expected from preliminary studies that nicotinamide (vitamin B3) could delay the onset of IDDM (Elliott & Chase, 1991; Pozzilli & Andreani, 1993), but that the preventive effect could vary from individual to individual (Herskowitz, Jackson, Soeldner, & Eisenbarth, 1989). Multicenter programs were launched to investigate the effect of this vitamin on the pathological process and on the biological markers in first-degree relatives (Nordenfelt, 1996). A second approach has been the prophylactic use of insulin to allow the remaining beta-cell mass to rest or to induce tolerance against beta-cell autoantigens. A clinical trial has begun in the USA (Keller, Eisenbarth, & Jackson, 1993).

8.11.2.2.3 Tertiary prevention

Tertiary prevention aims to prevent long-term complications despite the onset of diabetes. One approach has been pancreatic organ transplantation which has been shown to restore normoglycemia and to halt the progression of chronic complications (Robertson, 1992). However, the intervention is by no means a cure, and the required immunotherapy can cause serious unwanted effects, including increased risk of cancers. For these reasons, solitary pancreas transplantation is not a suitable treatment for diabetes. Pancreas transplantation is, however, sometimes performed in combination with a kidney graft in individuals with severe chronic complications. Since the 1970s, transplantation of insulin-producing islets has been studied as an alternative for pancreatic organ transplantation (Pipeleers, Keymeulen, & Korbutt, 1994). Several clinical trials have been initiated worldwide (Sutherland et al., 1996). Although many obstacles have to be overcome, transplantation of allogeneic (including human to human) or xenogeneic (including pig to human) donor tissue has the potential to treat IDDM in the early stages with a view to avoiding complications (Pipeleers et al., 1994).

8.11.3 NIDDM: ETIOLOGY, RISK FACTORS, AND PREVENTION

8.11.3.1 Risk Factors in NIDDM

NIDDM appears to be a complex multigenic-environmental disorder, with a strong genetic component. Theories about its pathogenesis implicate intrauterine malnutrition (Hales & Barker, 1992) and a common (little understood) metabolic disorder, Syndrome X (Reaven, 1988), which leads in differing circumstances to NIDDM—obesity, hypertension, or hyperuricemia (gout).

Familial clustering is a characteristic feature of NIDDM. Monozygotic twin studies show a concordance rate of over 90% (Newman et al., 1987; Pyke, 1979). The US National Health and

Examination Survey (Harris, 1984) showed that in people aged 35–74, about 35% of those with a medical history of diabetes had one or both parents with diabetes. Other studies have shown an even greater concordance for NIDDM in sibling pairs than parents and children (Beaty, Neel, & Fajans, 1982). The literature on risk of NIDDM in the offspring of affected people has been reviewed (Pierce, Keen, & Bradley, 1995). The reviewers concluded that having a parent with NIDDM increases offspring risk by between two- and fourfold, but a family history of NIDDM does not increase risk of IDDM. NIDDM risk increases if the affected parent is the mother rather than the father, or if both parents are affected, and with increasing age, and in certain racial groups.

NIDDM is more common in those who are overweight, people who take little exercise, and in racial groups other than northern European whites. The association between obesity and risk of NIDDM is strong, graded, and consistent. The literature has been comprehensively reviewed by Felber, Acheson, and Tappy (1992). The distribution of obesity, central or peripheral, has been shown to be a better predictor of later diabetes than the degree of adiposity. People with "central" or "male" type obesity are at much higher risk than those with "peripheral" obesity.

Epidemiological studies have shown a relationship between inactivity and NIDDM (Helmrich, Ragland, Taylor, Leung, & Paffenbarger, 1991; Taylor, Ram, Zimmet, Raper, & Ringrose, 1984), although these studies have been cross-sectional rather than prospective and hence caution is needed in deducing causality.

People with impaired glucose tolerance progress to NIDDM at a rate of between 2–6% per year, largely dependent on race (Jarret, Keen, Fuller, & McCartney, 1979; Saad et al., 1988). However, it is not possible to predict who will progress to NIDDM and who will revert to metabolic normality. Gestational diabetes can be regarded as an extreme form of impaired glucose tolerance in some pregnant women in response to the metabolic strain of pregnancy. After the baby is born, the diabetes may disappear, but it is likely to reappear in later life.

Certain racial groups, including Micronesians (e.g., Nauruans), native Americans (e.g., Pimas) Asian Indians, Mexican Americans, and Australian Aborigines, seem to be particularly prone to NIDDM, a fact which may be due to their genotype (Neel, 1982). Their susceptibility manifests itself when they move from a "traditional" lifestyle to a more "modern" one with increased availability of food and with reduction in the demand for physical exertion (Zimmet, 1992). Possibly, the genetic make-up of these people is adapted to survival in the face of variable supplies of food. This "thrifty genotype" (Neel, 1982) lays down fat stores very quickly when food is available and so facilitates survival during periods of famine. Such a genetic make-up would have clear evolutionary advantages in a "traditional" lifestyle such as that of the Australian Aboriginal hunter-gatherers. However, when these people move to a lifestyle characterized by a continuously plentiful food supply, they readily become overweight and develop NIDDM. Alternatively Hales and Barker (1992) have hypothesized that infants who are malnourished *in utero* develop physical changes in their pancreas and other organs, which in later life cause a decreased ability to cope with excess calories and so these people become overweight and develop NIDDM. This "thrifty phenotype" hypothesis could also account for these racial groups being particularly prone to NIDDM in the face of westernization.

8.11.3.2 Prevention of NIDDM

8.11.3.2.1 Primary prevention

There have been several studies testing the possibility of primary prevention of NIDDM using either pharmaceutical agents or behavioral methods (Erikksom & Lindegarde, 1991; Jarret, et al, 1979; Keen, Jarret, & McCartney, 1982; Knowler, Sartor, & Schersten, 1987; Sartor, Schersten, Carlstrom, Melander, & Persson, 1980). These have given somewhat contradictory results. However, Pan et al. (1994) reported the results of a randomized controlled trial of diet and exercise alone, or in combination, suggesting that all of these interventions reduced the rate of progression to NIDDM in people with impaired glucose tolerance in mainland China. In the light of these findings, a large multicenter primary prevention trial is being planned in the USA. The interventions are likely to include hypoglycemic drugs and/or behavioral methods aimed at the reduction of obesity and the promotion of exercise. The challenges of designing such a trial are considerable as potential recruits are likely to have preferences for drug or lifestyle intervention which will make a simple randomized controlled trial design inappropriate (Bradley, 1993).

8.11.3.2.2 Secondary prevention

The secondary prevention of NIDDM is under investigation by the UK Prospective

Diabetes Study Group (UKPDS) who are investigating the effects of early treatment regimens for NIDDM (UKPDS VIII, 1991).

8.11.3.2.3 Tertiary prevention
